Foreword

This third edition cancels and replaces the second edition. Changes from the previous edition include the addition of the following features:

- Pragma directives
- Anonymous methods
- Static classes
- Partial declarations
- Allowing `set` and `get` accessors for properties and indexers to have different accessibility.
- Generic types and methods
- Iterators
- Nullable types
Introduction

This International Standard is based on a submission from Hewlett-Packard, Intel, and Microsoft, that describes a language called C#, which was developed within Microsoft. The principal inventors of this language were Anders Hejlsberg, Scott Wiltamuth, and Peter Golde. The first widely distributed implementation of C# was released by Microsoft in July 2000, as part of its .NET Framework initiative.

Ecma Technical Committee 39 (TC39) Task Group 2 (TG2) was formed in September 2000, to produce a standard for C#. Another Task Group, TG3, was also formed at that time to produce a standard for a library and execution environment called Common Language Infrastructure (CLI). (CLI is based on a subset of the .NET Framework.) Although Microsoft’s implementation of C# relies on CLI for library and runtime support, other implementations of C# need not, provided they support an alternate way of getting at the minimum CLI features required by this C# standard.

As the definition of C# evolved, the goals used in its design were as follows:

- C# is intended to be a simple, modern, general-purpose, object-oriented programming language.
- The language, and implementations thereof, should provide support for software engineering principles such as strong type checking, array bounds checking, detection of attempts to use uninitialized variables, and automatic garbage collection. Software robustness, durability, and programmer productivity are important.
- The language is intended for use in developing software components suitable for deployment in distributed environments.
- Source code portability is very important, as is programmer portability, especially for those programmers already familiar with C and C++.
- Support for internationalization is very important.
- C# is intended to be suitable for writing applications for both hosted and embedded systems, ranging from the very large that use sophisticated operating systems, down to the very small having dedicated functions.
- Although C# applications are intended to be economical with regard to memory and processing power requirements, the language was not intended to compete directly on performance and size with C or assembly language.

The following companies and organizations have participated in the development of this standard, and their contributions are gratefully acknowledged: ActiveState, Borland, CSK Corp., Hewlett-Packard, IBM, Intel, IT University of Copenhagen, Jagersoft (UK), Microsoft, Mountain View Compiler, Monash University (AUS), Netscape, Novell, Pixo, Plum Hall, Sun, and the University of Canterbury (NZ).

The development of this version of the standard started in January 2003.
1. Scope

This International Standard specifies the form and establishes the interpretation of programs written in the C# programming language. It specifies

- The representation of C# programs;
- The syntax and constraints of the C# language;
- The semantic rules for interpreting C# programs;
- The restrictions and limits imposed by a conforming implementation of C#.

This International Standard does not specify

- The mechanism by which C# programs are transformed for use by a data-processing system;
- The mechanism by which C# applications are invoked for use by a data-processing system;
- The mechanism by which input data are transformed for use by a C# application;
- The mechanism by which output data are transformed after being produced by a C# application;
- The size or complexity of a program and its data that will exceed the capacity of any specific data-processing system or the capacity of a particular processor;
- All minimal requirements of a data-processing system that is capable of supporting a conforming implementation.
2. Conformance

Conformance is of interest to the following audiences:

- Those designing, implementing, or maintaining C# implementations.
- Governmental or commercial entities wishing to procure C# implementations.
- Testing organizations wishing to provide a C# conformance test suite.
- Programmers wishing to port code from one C# implementation to another.
- Educators wishing to teach Standard C#.
- Authors wanting to write about Standard C#.

As such, conformance is most important, and the bulk of this International Standard is aimed at specifying the characteristics that make C# implementations and C# programs conforming ones.

The text in this International Standard that specifies requirements is considered normative. All other text in this specification is informative; that is, for information purposes only. Unless stated otherwise, all text is normative. Normative text is further broken into required and conditional categories. Conditionally normative text specifies requirements for a feature such that if that feature is provided, its syntax and semantics must be exactly as specified.

Undefined behavior is indicated in this International Standard only by the words “undefined behavior.”

A strictly conforming program shall use only those features of the language specified in this International Standard as being required. (This means that a strictly conforming program cannot use any conditionally normative feature.) It shall not produce output dependent on any unspecified, undefined, or implementation-defined behavior.

A conforming implementation of C# must accept any strictly conforming program.

A conforming implementation of C# must provide and support all the types, values, objects, properties, methods, and program syntax and semantics described in the normative (but not the conditionally normative) parts in this International Standard.

A conforming implementation of C# shall interpret characters in conformance with the Unicode Standard, Version 3.0, and ISO/IEC 10646-1. Conforming implementations must accept Unicode source files encoded with the UTF-8 encoding form.

A conforming implementation of C# shall not successfully translate source containing a #error preprocessing directive unless it is part of a group skipped by conditional compilation.

A conforming implementation of C# shall produce at least one diagnostic message if the source program violates any rule of syntax, or any negative requirement (defined as a “shall” or “shall not” or “error” or “warning” requirement), unless that requirement is marked with the words “no diagnostic is required”.

A conforming implementation of C# is permitted to provide additional types, values, objects, properties, and methods beyond those described in this International Standard, provided they do not alter the behavior of any strictly conforming program. Conforming implementations are required to diagnose programs that use extensions that are ill formed according to this International Standard. Having done so, however, they can compile and execute such programs. (The ability to have extensions implies that a conforming implementation reserves no identifiers other than those explicitly reserved in this International Standard.)
A conforming implementation of C# shall be accompanied by a document that defines all implementation-defined characteristics, and all extensions.

A conforming implementation of C# shall support the class library documented in Annex D. This library is included by reference in this International Standard.

A *conforming program* is one that is acceptable to a conforming implementation. (Such a program is permitted to contain extensions or conditionally normative features.)
3. Normative references

The following normative documents contain provisions, which, through reference in this text, constitute provisions of this International Standard. For dated references, subsequent amendments to, or revisions of, any of these publications do not apply. However, parties to agreements based on this International Standard are encouraged to investigate the possibility of applying the most recent editions of the normative documents indicated below. For undated references, the latest edition of the normative document referred to applies. Members of ISO and IEC maintain registers of currently valid International Standards.

ISO 31.11:1992, Quantities and units — Part 11: Mathematical signs and symbols for use in the physical sciences and technology.

ISO/IEC 10646 (all parts), Information technology — Universal Multiple-Octet Coded Character Set (UCS).

4. Definitions

For the purposes of this International Standard, the following definitions apply. Other terms are defined where they appear in italic type or on the left side of a syntax rule. Terms explicitly defined in this International Standard are not to be presumed to refer implicitly to similar terms defined elsewhere. Terms not defined in this International Standard are to be interpreted according to ISO/IEC 2382.1. Mathematical symbols not defined in this International Standard are to be interpreted according to ISO 31.11.

Application — refers to an assembly that has an entry point (§10.1). When an application is run, a new application domain is created. Several different instantiations of an application can exist on the same machine at the same time, and each has its own application domain.

Application domain — an entity that enables application isolation by acting as a container for application state. An application domain acts as a container and boundary for the types defined in the application and the class libraries it uses. Types loaded into one application domain are distinct from the same type loaded into another application domain, and instances of objects are not directly shared between application domains. For instance, each application domain has its own copy of static variables for these types, and a static constructor for a type is run at most once per application domain. Implementations are free to provide implementation-specific policy or mechanisms for the creation and destruction of application domains.

Argument — an expression in the comma-separated list bounded by the parentheses in a method or instance constructor call expression or bounded by the square brackets in an element access expression. It is also known as an actual argument.

Assembly — refers to one or more files that are output by the compiler as a result of program compilation. An assembly is a configured set of loadable code modules and other resources that together implement a unit of functionality. An assembly can contain types, the executable code used to implement these types, and references to other assemblies. The physical representation of an assembly is not defined by this specification. Essentially, an assembly is the output of the compiler.

Behavior — external appearance or action.

Behavior, implementation-defined — unspecified behavior where each implementation documents how the choice is made.

Behavior, undefined — behavior, upon use of a non-portable or erroneous construct or of erroneous data, for which this International Standard imposes no requirements. [Possible handling of undefined behavior ranges from ignoring the situation completely with unpredictable results, to behaving during translation or execution in a documented manner characteristic of the environment (with or without the issuance of a diagnostic message), to terminating a translation or execution (with the issuance of a diagnostic message)].

Behavior, unspecified — behavior where this International Standard provides two or more possibilities and imposes no further requirements on which is chosen in any instance.

Class library — refers to an assembly that can be used by other assemblies. Use of a class library does not cause the creation of a new application domain. Instead, a class library is loaded into the application domain that uses it. For instance, when an application uses a class library, that class library is loaded into the application domain for that application. If an application uses a class library A that itself uses a class library B, then both A and B are loaded into the application domain for the application.

Diagnostic message — a message belonging to an implementation-defined subset of the implementation’s output messages.

Error, compile-time — an error reported during program translation.

Exception — an error condition that is outside the ordinary expected behavior.
**Implementation** — particular set of software (running in a particular translation environment under particular control options) that performs translation of programs for, and supports execution of methods in, a particular execution environment.

**Namespace** — a logical organizational system that provides a way of presenting program elements that are exposed to other programs.

**Parameter** — a variable declared as part of a method, instance constructor, operator, or indexer definition, which acquires a value on entry to that function member. It is also known as a *formal parameter*.

**Program** — refers to one or more source files that are presented to the compiler. Essentially, a program is the input to the compiler.

**Program, valid** — a C# program constructed according to the syntax rules and diagnosable semantic rules.

**Program instantiation** — the execution of an application.

**Recommended practice** — specification that is strongly recommended as being aligned with the intent of the standard, but that might be impractical for some implementations.

**Source file** — an ordered sequence of Unicode characters. Source files typically have a one-to-one correspondence with files in a file system, but this correspondence is not required.

**Unsafe code** — code that is permitted to perform such lower-level operations as declaring and operating on pointers, performing conversions between pointers and integral types, and taking the address of variables. Such operations provide functionality such as permitting interfacing with the underlying operating system, accessing a memory-mapped device, or implementing a time-critical algorithm.

**Warning, compile-time** — an informational message reported during program translation, that is intended to identify a potentially questionable usage of a program element.
5. Notational conventions

Lexical and syntactic grammars for C# are interspersed throughout this specification. The lexical grammar defines how characters can be combined to form tokens (§9.4), the minimal lexical elements of the language. The syntactic grammar defines how tokens can be combined to make valid C# programs.

Grammar productions include both non-terminal and terminal symbols. In grammar productions, non-terminal symbols are shown in italic type, and terminal symbols are shown in a fixed-width font. Each non-terminal is defined by a set of productions. The first line of a set of productions is the name of the non-terminal, followed by one or two colons. One colon is used for a production in the syntactic grammar, two colons for a production in the lexical grammar. Each successive indented line contains the right-hand side for a production that has the non-terminal symbol as the left-hand side. For example:

```plaintext
class-modifier:
   new
   public
   protected
   internal
   private
   abstract
   sealed
   static
```

defines the `class-modifier` non-terminal as having seven productions.

Alternatives are normally listed on separate lines, as shown above, though in cases where there are many alternatives, the phrase “one of” precedes a list of the options. This is simply shorthand for listing each of the alternatives on a separate line. For example:

```plaintext
decimal-digit: one of
   0 1 2 3 4 5 6 7 8 9
```

is equivalent to:

```plaintext
decimal-digit:
   0
   1
   2
   3
   4
   5
   6
   7
   8
   9
```

A subscripted suffix “opt”, as in `identifier_opt`, is used as shorthand to indicate an optional symbol. The example:

```plaintext
for-statement:
   for ( for-initializer_opt ; for-condition_opt ; for-iterator_opt ) embedded-statement
```

is equivalent to:
for-statement:
  for ( ; ; ) embedded-statement
  for ( for-initializer ; ; ) embedded-statement
  for ( ; for-condition ; ) embedded-statement
  for ( ; ; for-iterator ) embedded-statement
  for ( for-initializer ; for-condition ; ) embedded-statement
  for ( ; for-condition ; for-iterator ) embedded-statement
  for ( for-initializer ; ; for-iterator ) embedded-statement
  for ( for-initializer ; for-condition ; for-iterator ) embedded-statement

All terminal characters are to be understood as the appropriate Unicode character from the range U+0020 to U+007F, as opposed to any similar-looking characters from other Unicode character ranges.

7. General description

This text is informative.

This International Standard is intended to be used by implementers, academics, and application programmers. As such, it contains a considerable amount of explanatory material that, strictly speaking, is not necessary in a formal language specification.

This standard is divided into the following subdivisions:

1. Front matter (clauses 1–7);
2. Language overview (clause 8);
3. The language syntax, constraints, and semantics (clauses 9–27);
4. Annexes

Examples are provided to illustrate possible forms of the constructions described. References are used to refer to related clauses. Notes are provided to give advice or guidance to implementers or programmers. Annexes provide additional information and summarize the information contained in this International Standard.

Clauses 1–5, 9–26, the beginning of 27, and most of annex D form a normative part of this standard; all of clause 27 with the exception of the beginning is conditionally normative; and Foreword, Introduction, clauses 6–8, annexes A, B, C, E, F, and part of D, notes, examples, and the index are informative.

End of informative text.

Informative text is indicated in the following ways:

1. Whole or partial clauses or annexes delimited by “This clause/text is informative” and “End of informative text”.
2. [Example: The following example … code fragment, possibly with some narrative … end example]
3. [Note: narrative … end note]

All text not marked as being informative is normative.
8. Language overview

This clause is informative.

C# (pronounced “C Sharp”) is a simple, modern, object oriented, and type-safe programming language. It will immediately be familiar to C and C++ programmers. C# combines the high productivity of Rapid Application Development (RAD) languages and the raw power of C++.

The rest of this clause describes the essential features of the language. While later clauses describe rules and exceptions in a detail-oriented and sometimes mathematical manner, this clause strives for clarity and brevity at the expense of completeness. The intent is to provide the reader with an introduction to the language that will facilitate the writing of early programs and the reading of later clauses.

8.1 Getting started

The canonical “hello, world” program can be written as follows:

```csharp
using System;

class Hello
{
    static void Main()
    {
        Console.WriteLine("hello, world");
    }
}
```

The source code for a C# program is typically stored in one or more text files with a file extension of `.cs`, as in `hello.cs`. Using a command-line compiler, such a program can be compiled with a command line like `csc hello.cs` which produces an application named `hello.exe`. The output produced by this application when it is run is:

```
hello, world
```

Close examination of this program is illuminating:

- The `using System;` directive references a namespace called `System` that is provided by the Common Language Infrastructure (CLI) class library. This namespace contains the `Console` class referred to in the `Main` method. Namespaces provide a hierarchical means of organizing the elements of one or more programs. A using directive enables unqualified use of the types that are members of the namespace. The “hello, world” program uses `Console.WriteLine` as shorthand for `System.Console.WriteLine`.
- The `Main` method is a member of the class `Hello`. It has the `static` modifier, and so it is a method on the class `Hello` rather than on instances of this class.
- The entry point for an application—the method that is called to begin execution—is always a static method named `Main`.
- The “hello, world” output is produced using a class library. This standard does not include a class library. Instead, it references the class library provided by CLI.

For C and C++ developers, it is interesting to note a few things that do not appear in the “hello, world” program:

- The program does not use a global method for `Main`. Methods and variables are not supported at the global level; such elements are always contained within type declarations (e.g., class and struct declarations).
The program does not use either “::” or “->” operators. The “::” token is used only to separate a namespace alias from a member of the namespace, and the “->” operator is used in only a small fraction of programs (which involve unsafe code). The separator “.” is used in compound names such as `Console.WriteLine`.

The program does not contain forward declarations. Forward declarations are never needed, as declaration order is not significant.

The program does not use `#include` to import program text. Dependencies among programs are handled symbolically rather than textually. This approach eliminates barriers between applications written using multiple languages. For example, the `Console` class need not be written in C#.

8.2 Types
C# supports two kinds of types: value types and reference types. Value types include simple types (e.g., `char`, `int`, and `float`), enum types, and struct types. Reference types include class types, interface types, delegate types, and array types.

Value types differ from reference types in that variables of the value types directly contain their data, whereas variables of the reference types store references to objects. With reference types, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With value types, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other.

The example
```csharp
using System;
struct Struct1
{
    public int Value;
}
class Class1
{
    public int Value = 0;
}
class Test
{
    static void Main()
    {
        Struct1 val1 = new Struct1();
        Struct1 val2 = val1;
        val2.Value = 123;
        Class1 ref1 = new Class1();
        Class1 ref2 = ref1;
        ref2.Value = 123;
        Console.WriteLine("Values: {0}, {1}", val1.Value, val2.Value);
        Console.WriteLine("Refs: {0}, {1}", ref1.Value, ref2.Value);
    }
}
```
shows this difference. The output produced is
```
Values: 0, 123
Refs: 123, 123
```

The assignment to a field of the local variable `val2` does not impact the local variable `val1` because both local variables are of a value type (the type `Struct1`) and each local variable of a value type has its own storage. In contrast, the assignment `ref2.Value = 123;` affects the object that both `ref1` and `ref2` reference.

The lines
```
Console.WriteLine("Values: {0}, {1}", val1.Value, val2.Value);
Console.WriteLine("Refs: {0}, {1}", ref1.Value, ref2.Value);
```

deserve further comment, as they demonstrate some of the string formatting behavior of
Console.WriteLine, which, in fact, takes a variable number of arguments. The first argument is a string,
which can contain numbered placeholders like {0} and {1}. Each placeholder refers to a trailing argument
with {0} referring to the second argument, {1} referring to the third argument, and so on. Before the output
is sent to the console, each placeholder is replaced with the formatted value of its corresponding argument.

Developers can define new value types through enum and struct declarations, and can define new reference
types via class, interface, and delegate declarations. The example

```csharp
using System;
public enum Color
{
    Red, Blue, Green
}
public struct Point
{
    public int x, y;
}
public interface IBase
{
    void F();
}
public interface IDerived: IBase
{
    void G();
}
public class A
{
    protected virtual void H() {
        Console.WriteLine("A.H");
    }
}
public class B: A, IDerived
{
    public void F() {
        Console.WriteLine("B.F, implementation of IDerived.F");
    }
    public void G() {
        Console.WriteLine("B.G, implementation of IDerived.G");
    }
    override protected void H() {
        Console.WriteLine("B.H, override of A.H");
    }
}
public delegate void EmptyDelegate();
```

shows an example of each kind of type declaration. Later clauses describe type declarations in detail.

### 8.2.1 Predefined types

C# provides a set of predefined types, most of which will be familiar to C and C++ developers.

The predefined reference types are `object` and `string`. The type `object` is the ultimate base type of all
other types. The type `string` is used to represent Unicode string values. Values of type `string` are
immutable.

The predefined value types include signed and unsigned integral types, floating-point types, and the types
`bool`, `char`, and `decimal`. The signed integral types are `sbyte`, `short`, `int`, and `long`; the unsigned
integral types are `byte`, `ushort`, `uint`, and `ulong`; and the floating-point types are `float` and `double`.

---

8 Language overview
The `bool` type is used to represent Boolean values: values that are either true or false. The inclusion of `bool` makes it easier to write self-documenting code; it also helps eliminate the all-too-common C++ coding error in which a developer mistakenly uses `"="` when `"=="` should have been used. In C#, the example

```csharp
int i = ...;
F(i);
if (i = 0)  // Bug: the test should be (i == 0)
    G();
```

results in a compile-time error because the expression `i = 0` is of type `int`, and `if` statements require an expression of type `bool`.

The `char` type is used to represent Unicode code units. A variable of type `char` represents a single 16-bit Unicode code unit.

The `decimal` type is appropriate for calculations in which rounding errors caused by floating point representations are unacceptable. Common examples include financial calculations such as tax computations and currency conversions. The `decimal` type provides for at least 28 significant digits.

The table below lists the predefined types, and shows how to write literal values for each of them.

</tr>
</tbody>
</table>

Each of the predefined types is shorthand for a system-provided type. For example, the keyword `int` refers to the struct `System.Int32`. As a matter of style, use of the keyword is favored over use of the complete system type name.

Predefined value types such as `int` are treated specially in a few ways but are for the most part treated exactly like other structs. Operator overloading enables developers to define new struct types that behave much like the predefined value types. For instance, a `Digit` struct can support the same mathematical
operations as the predefined integral types, and can define conversions between `Digit` and predefined types.

The predefined types employ operator overloading themselves. For example, the comparison operators `==` and `!=` have different semantics for different predefined types:

- Two expressions of type `int` are considered equal if they represent the same integer value.
- Two expressions of type `object` are considered equal if both refer to the same object, or if both are `null`.
- Two expressions of type `string` are considered equal if the string instances have identical lengths and identical characters in each character position, or if both are `null`.

The example
```
using System;

class Test {
    static void Main() {
        string s = "Test";
        string t = string.Copy(s);
        Console.WriteLine(s == t);
        Console.WriteLine((object)s == (object)t);
    }
}
```
produces the output
```
True
False
```
because the first comparison compares two expressions of type `string`, and the second comparison compares two expressions of type `object`. (Note that when the Standard Library produces a string representation of a Boolean value, as is the case with `System.WriteLine` above, it uses “True” and “False”, while the corresponding C# language Boolean literals are spelled `true` and `false`.)

### 8.2.2 Conversions

The predefined types also have predefined conversions. For instance, conversions exist between the predefined types `int` and `long`. C# differentiates between two kinds of conversions: *implicit conversions* and *explicit conversions*. Implicit conversions are supplied for conversions that can safely be performed without careful scrutiny. For instance, the conversion from `int` to `long` is an implicit conversion. This conversion always succeeds, and never results in a loss of information. The following example
```
using System;

class Test {
    static void Main() {
        int intValue = 123;
        long longValue = intValue;
        Console.WriteLine("{0}, {1}", intValue, longValue);
    }
}
```
imply converts an `int` to a `long`.

In contrast, explicit conversions are performed with a cast expression. The example
```
using System;
```
class Test
{
    static void Main()
    {
        long longValue = Int64.MaxValue;
        int intValue = (int) longValue;
        Console.WriteLine("(int) {0} = {1}", longValue, intValue);
    }
}

uses an explicit conversion to convert a long to an int. The output is:
(int) 9223372036854775807 = -1

because an overflow occurs. Cast expressions permit the use of both implicit and explicit conversions.

8.2.3 Array types
Arrays can be single-dimensional or multi-dimensional. Both “rectangular” and “jagged” arrays are supported.

Single-dimensional arrays are the most common type. The example
using System;
class Test
{
    static void Main()
    {
        int[] arr = new int[5];
        for (int i = 0; i < arr.Length; i++)
            arr[i] = i * i;
        for (int i = 0; i < arr.Length; i++)
            Console.WriteLine("arr[{0}] = {1}", i, arr[i]);
    }
}

creates a single-dimensional array of int values, initializes the array elements, and then prints each of them out. The output produced is:
arr[0] = 0
arr[1] = 1
arr[2] = 4
arr[3] = 9
arr[4] = 16

The type int[] used in the previous example is an array type. Array types are written using a non-array-type followed by one or more rank specifiers. The example
class Test
{
    static void Main()
    {
        int[] a1;   // single-dimensional array of int
        int[,] a2;   // 2-dimensional array of int
        int[,,] a3;   // 3-dimensional array of int
        int[,][,] j2;   // "jagged" array: array of (array of int)
        int[,,][,,] j3;  // array of (array of (array of int))
    }
}

shows a variety of local variable declarations that use array types with int as the element type.

Array types are reference types, and so the declaration of an array variable merely sets aside space for the reference to the array. Array instances are actually created via array initializers and array creation expressions. The example
class Test
{
    static void Main()
    {
        int[] a1 = new int[] {1, 2, 3};
        int[,] a2 = new int[,] {{1, 2, 3}, {4, 5, 6}};
        int[,,] a3 = new int[10, 20, 30];
        int[][] j2 = new int[3][];
        j2[0] = new int[] {1, 2, 3};
        j2[1] = new int[] {1, 2, 3, 4, 5, 6};
        j2[2] = new int[] {1, 2, 3, 4, 5, 6, 7, 8, 9};
    }
}

shows a variety of array creation expressions. The variables a1, a2 and a3 denote rectangular arrays, and
the variable j2 denotes a jagged array. It should be no surprise that these terms are based on the shapes of
the arrays. Rectangular arrays always have a rectangular shape. Given the length of each dimension of the
array, its rectangular shape is clear. For example, the lengths of a3’s three dimensions are 10, 20, and 30,
respectively, and it is easy to see that this array contains 10*20*30 elements.

In contrast, the variable j2 denotes a “jagged” array, or an “array of arrays”. Specifically, j2 denotes an
array of an array of int, or a single-dimensional array of type int[]. Each of these int[] variables can be
initialized individually, and this allows the array to take on a jagged shape. The example gives each of the
int[] arrays a different length. Specifically, the length of j2[0] is 3, the length of j2[1] is 6, and the

[Note: In C++, an array declared as int x[3][5][7] would be considered a three dimensional rectangular
array, while in C#, the declaration int[] [] [] declares a jagged array type. end note]

The element type and shape of an array—including whether it is jagged or rectangular, and the number of
dimensions it has—are part of its type. On the other hand, the size of the array—as represented by the length
of each of its dimensions—is not part of an array’s type. This split is made clear in the language syntax, as
the length of each dimension is specified in the array creation expression rather than in the array type. For
instance the declaration

    int[,,] a3 = new int[10, 20, 30];

has an array type of int[,,] and an array creation expression of new int[10, 20, 30].

For local variable and field declarations, a shorthand form is permitted so that it is not necessary to re-state
the array type. For instance, the example

    int[] a1 = new int[] {1, 2, 3};

can be shortened to

    int[] a1 = {1, 2, 3};

without any change in program semantics.

The context in which an array initializer such as {1, 2, 3} is used determines the type of the array being
initialized. The example

    class Test
    {
        static void Main()
        {
            short[] a = {1, 2, 3};
            int[] b = {1, 2, 3};
            long[] c = {1, 2, 3};
        }
    }

shows that the same array initializer syntax can be used for several different array types. Because context is
required to determine the type of an array initializer, it is not possible to use an array initializer in an
expression context without explicitly stating the type of the array.
8.2.4 Type system unification

C# provides a “unified type system”. All types—including value types—derive from the type object. It is possible to call object methods on any value, even values of “primitive” types such as int. The example

```csharp
using System;
class Test
{
    static void Main()
    {
        Console.WriteLine(3.ToString());
    }
}
```
calls the object-defined ToString method on an integer literal, resulting in the output “3”.

The example

```csharp
class Test
{
    static void Main()
    {
        int i = 123;
        object o = i;  // boxing
        int j = (int) o; // unboxing
    }
}
```
is more interesting. An int value can be converted to object and back again to int. This example shows both boxing and unboxing. When a variable of a value type needs to be converted to a reference type, an object box is allocated to hold the value, and the value is copied into the box. Unboxing is just the opposite. When an object box is cast back to its original value type, the value is copied out of the box and into the appropriate storage location.

This type system unification provides value types with the benefits of object-ness without introducing unnecessary overhead. For programs that don’t need int values to act like objects, int values are simply 32-bit values. For programs that need int values to behave like objects, this capability is available on demand. This ability to treat value types as objects bridges the gap between value types and reference types that exists in most languages. For example, a Stack class can provide Push and Pop methods that take and return object values.

```csharp
public class Stack
{
    public object Pop() {...}
    public void Push(object o) {...}
}
```

Because C# has a unified type system, the Stack class can be used with elements of any type, including value types like int.

8.3 Variables and parameters

Variables represent storage locations. Every variable has a type that determines what values can be stored in the variable. Local variables are variables that are declared in function members such as methods, properties, and indexers. A local variable is defined by specifying a type name and a declarator that specifies the variable name and an optional initial value, as in:

```csharp
int a;
int b = 1;
```

but it is also possible for a local variable declaration to include multiple declarators. The declarations of a and b can be rewritten as:

```csharp
int a, b = 1;
```

A variable shall be assigned before its value can be obtained. The example
class Test
{
    static void Main()
    {
        int a;
        int b = 1;
        int c = a + b; // error, a not yet assigned
    }
}

results in a compile-time error because it attempts to use the variable a before it is assigned a value. The rules governing definite assignment are defined in §12.3.

A field (§17.4) is a variable that is associated with a class or struct, or an instance of a class or struct. A field declared with the static modifier defines a static variable, and a field declared without this modifier defines an instance variable. A static field is associated with a type, whereas an instance variable is associated with an instance. The example

using Personnel.Data;
class Employee
{  
    private static DataSet ds;
    public string Name;
    public decimal Salary;
}

demonstrates an Employee class that has a private static variable and two public instance variables.

Formal parameter declarations also define variables. There are four kinds of parameters: value parameters, reference parameters, output parameters, and parameter arrays.

A value parameter is used for “in” parameter passing, in which the value of an argument is passed into a method, and modifications of the parameter do not impact the original argument. A value parameter refers to its own variable, one that is distinct from the corresponding argument. This variable is initialized by copying the value of the corresponding argument. The example

using System;
class Test
{  
    static void F(int p) {  
        Console.WriteLine("p = \{0\}", p);
        p++;
    }
    static void Main() {  
        int a = 1;
        Console.WriteLine("pre: \{0\}", a);
        F(a);
        Console.WriteLine("post: \{0\}", a);
    }
}

demonstrates a method F that has a value parameter named p. The example produces the output:

pre:  a = 1
p = 1
post: a = 1

even though the value parameter p is modified.

A reference parameter is used for “by reference” parameter passing, in which the parameter acts as an alias for a caller-provided argument. A reference parameter does not itself define a variable, but rather refers to the variable of the corresponding argument. Modifications of a reference parameter impact the corresponding argument. A reference parameter is declared with a ref modifier. The example

using System;
class Test
{
    static void Swap(ref int a, ref int b) {
        int t = a;
        a = b;
        b = t;
    }
    static void Main() {
        int x = 1;
        int y = 2;
        Console.WriteLine("pre:  x = {0}, y = {1}", x, y);
        Swap(ref x, ref y);
        Console.WriteLine("post: x = {0}, y = {1}", x, y);
    }
}

shows a `Swap` method that has two reference parameters. The output produced is:

pre:  x = 1, y = 2
post: x = 2, y = 1

The `ref` keyword shall be used in both the declaration of the formal parameter and in uses of it. The use of `ref` at the call site calls special attention to the parameter, so that a developer reading the code will understand that the value of the argument could change as a result of the call.

An output parameter is similar to a reference parameter, except that the initial value of the caller-provided argument is unimportant. An output parameter is declared with an `out` modifier. The example

```
using System;

class Test
{
    static void Divide(int a, int b, out int result, out int remainder) {
        result = a / b;
        remainder = a % b;
    }
    static void Main() {
        for (int i = 1; i < 10; i++)
            for (int j = 1; j < 10; j++) {
                int ans, r;
                Divide(i, j, out ans, out r);
                Console.WriteLine("{0} / {1} = {2}r{3}", i, j, ans, r);
            }
    }
}
```

shows a `Divide` method that includes two output parameters—one for the result of the division and another for the remainder.

For value, reference, and output parameters, there is a one-to-one correspondence between caller-provided arguments and the parameters used to represent them. A parameter array enables a many-to-one relationship: many arguments can be represented by a single parameter array. In other words, parameter arrays enable variable length argument lists.

A parameter array is declared with a `params` modifier. There can be only one parameter array for a given method, and it shall always be the last parameter specified. The type of a parameter array is always a single dimensional array type. A caller can either pass a single argument of this array type, or any number of arguments of the element type of this array type. For instance, the example

```
using System;
```
class Test
{
    static void F(params int[] args) {
        Console.WriteLine("# of arguments: {0}", args.Length);
        for (int i = 0; i < args.Length; i++)
            Console.WriteLine("\targs[{0}] = {1}", i, args[i]);
    }
    static void Main() {
        F();
        F(1);
        F(1, 2);
        F(1, 2, 3);
        F(new int[] {1, 2, 3, 4});
    }
}

shows a method F that takes a variable number of int arguments, and several invocations of this method. The output is:

# of arguments: 0
# of arguments: 1
  args[0] = 1
# of arguments: 2
  args[0] = 1
  args[1] = 2
# of arguments: 3
  args[0] = 1
  args[1] = 2
  args[2] = 3
# of arguments: 4
  args[0] = 1
  args[1] = 2
  args[2] = 3
  args[3] = 4

Most of the examples presented in this introduction use the WriteLine method of the Console class. The argument substitution behavior of this method, as exhibited in the example

```csharp
int a = 1, b = 2;
Console.WriteLine("a = {0}, b = {1}", a, b);
```

is accomplished using a parameter array. The WriteLine method provides several overloaded methods for the common cases in which a small number of arguments are passed, and one method that uses a parameter array.

namespace System
{
    public class Console
    {
        public static void WriteLine(string s) { .. }
        public static void WriteLine(string s, object a) { .. }
        public static void WriteLine(string s, object a, object b) { .. }
        ..
        public static void WriteLine(string s, params object[] args) { .. }
    }
}

8.4 Automatic memory management

Manual memory management requires developers to manage the allocation and de-allocation of blocks of memory. Manual memory management can be both time-consuming and difficult. In C#, automatic memory management is provided so that developers are freed from this burdensome task. In the vast majority of cases, automatic memory management increases code quality and enhances developer productivity without negatively impacting either expressiveness or performance.

The example

```csharp
using System;
```
public class Stack
{
    private Node first = null;
    public bool Empty {
        get {
            return (first == null);
        }
    }
    public object Pop() {
        if (first == null)
            throw new Exception("Can't Pop from an empty Stack.");
        else {
            object temp = first.Value;
            first = first.Next;
            return temp;
        }
    }
    public void Push(object o) {
        first = new Node(o, first);
    }
}

class Node
{
    public Node Next;
    public object Value;
    public Node(object value): this(value, null) {} 
    public Node(object value, Node next) {
        Next = next;
        Value = value;
    }
}

shows a Stack class implemented as a linked list of Node instances. Node instances are created in the Push method and are garbage collected when no longer needed. A Node instance becomes eligible for garbage collection when it is no longer possible for any code to access it. For instance, when an item is removed from the Stack, the associated Node instance becomes eligible for garbage collection.

The example

class Test
{
    static void Main() {
        Stack s = new Stack();
        for (int i = 0; i < 10; i++)
            s.Push(i);
        s = null;
    }
}

shows code that uses the Stack class. A Stack is created and initialized with 10 elements, and then assigned the value null. Once the variable s is assigned null, the Stack and the associated 10 Node instances become eligible for garbage collection. The garbage collector is permitted to clean up immediately, but is not required to do so.

The garbage collector underlying C# might work by moving objects around in memory, but this motion is invisible to most C# developers. For developers who are generally content with automatic memory management but sometimes need fine-grained control or that extra bit of performance, C# provides the ability to write “unsafe” code. Such code can deal directly with pointer types and object addresses; however, C# requires the programmer to fix objects to temporarily prevent the garbage collector from moving them.

This “unsafe” code feature is in fact a “safe” feature from the perspective of both developers and users. Unsafe code shall be clearly marked in the code with the modifier unsafe, so developers can’t possibly use unsafe language features accidentally, and the compiler and the execution engine work together to ensure
that unsafe code cannot masquerade as safe code. These restrictions limit the use of unsafe code to situations
in which the code is trusted.

The example

```csharp
using System;

class Test
{
    static void WriteLocations(byte[] arr) {
        unsafe {
            fixed (byte* pArray = arr) {
                byte* pElem = pArray;
                for (int i = 0; i < arr.Length; i++) {
                    byte value = *pElem;
                    Console.WriteLine("arr[{0}] at 0x{1:X} is {2}",
                        i, (uint)pElem, value);
                    pElem++;
                }
            }
        }
    }
    
    static void Main() {
        byte[] arr = new byte[] {1, 2, 3, 4, 5};
        WriteLocations(arr);
    }
}
```

shows an unsafe block in a method named `WriteLocations` that fixes an array instance and uses pointer
manipulation to iterate over the elements. The index, value, and location of each array element are written to
the console. One possible example of output is:

```
arr[0] at 0x8E0360 is 1
arr[1] at 0x8E0361 is 2
arr[2] at 0x8E0362 is 3
arr[3] at 0x8E0363 is 4
arr[4] at 0x8E0364 is 5
```

but, of course, the exact memory locations can be different in different executions of the application.

### 8.5 Expressions

C# includes unary operators, binary operators, and one ternary operator. The following table summarizes the
operators, listing them in order of precedence from highest to lowest:
Subclause | Category | Operators
--- | --- | ---
14.5 | Primary | x.y f(x) a[x] x++ x-- new typeof checked unchecked
14.5.14 | Unary | + - ! ~ ++x --x (T)x
14.7 | Multiplicative | * / %
14.7 | Additive | + -
14.8 | Shift | << >>
14.9 | Relational and type-testing | < > <= >= is as
14.9 | Equality | == !=
14.10 | Logical AND | &
14.10 | Logical XOR | ^
14.10 | Logical OR | |
14.11 | Conditional AND | &&
14.11 | Conditional OR | ||
14.13 | Conditional | ?:
14.14 | Assignment | = *= /= %= += -= <<= >>= &= ^= |=

When an expression contains multiple operators, the **precedence** of the operators controls the order in which the individual operators are evaluated. For example, the expression \( x + y \times z \) is evaluated as \( x + (y \times z) \) because the \( \times \) operator has higher precedence than the \( + \) operator.

When an operand occurs between two operators with the same precedence, the **associativity** of the operators controls the order in which the operations are performed:

- Except for the assignment operators, all binary operators are **left-associative**, meaning that operations are performed from left to right. For example, \( x + y + z \) is evaluated as \( (x + y) + z \).
- The assignment operators and the conditional operator (?:) are **right-associative**, meaning that operations are performed from right to left. For example, \( x = y = z \) is evaluated as \( x = (y = z) \).

Precedence and associativity can be controlled using parentheses. For example, \( x + y \times z \) first multiplies \( y \) by \( z \) and then adds the result to \( x \), but \( (x + y) \times z \) first adds \( x \) and \( y \) and then multiplies the result by \( z \).

### 8.6 Statements

C# borrows most of its statements directly from C and C++, though there are some noteworthy additions and modifications. The table below lists the kinds of statements that can be used, and provides an example for each.
<table>
<thead>
<tr>
<th>Statement</th>
<th>Example</th>
</tr>

</table>
| Statement lists and block statements         | static void Main() {  
|                                              | F();

|                                              | {  
|                                              | H();  
|                                              | I();

8.7 Classes

Class declarations define new reference types. A class can inherit from another class, and can implement interfaces. Generic class declarations (§25.1) have one or more type parameters.

Class members can include constants, fields, methods, properties, events, indexers, operators, instance constructors, finalizers, static constructors, and nested type declarations. Each member has an associated accessibility (§10.5), which controls the regions of program text that are able to access the member. There are five possible forms of accessibility. These are summarized in the table below.

<table>
<thead>
<tr>
<th>Form</th>
<th>Intuitive meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>public</td>
<td>Access not limited</td>
</tr>
<tr>
<td>protected</td>
<td>Access limited to the containing class or types derived from the containing class</td>
</tr>
<tr>
<td>internal</td>
<td>Access limited to this program</td>
</tr>
<tr>

<td>Access limited to this program or types derived from the containing class</td>
</tr>
<tr>

<td>Access limited to the containing type</td>
</tr>
</tbody>
</table>

The example

```csharp
using System;
class MyClass
{
    public const int MyConst = 12;
    public int MyField = 34;
    public static int MyStaticField = 34;
    public void MyMethod() {
        Console.WriteLine("MyClass.MyMethod");
    }
    public int MyProperty {
        get {
            return MyField;
        }
    }
}
```
C# LANGUAGE SPECIFICATION

```csharp
set {
    MyField = value;
}
}
public event EventHandler MyEvent;
public int this[int index] {
    get {
        return 0;
    }
    set {
        Console.WriteLine("this[{0}] = {1}", index, value);
    }
}
public static MyClass operator+(MyClass a, MyClass b) {
    return new MyClass(a.MyField + b.MyField);
}
public MyClass() {
    Console.WriteLine("Instance constructor");
}
public MyClass(int value) {
    MyField = value;
    Console.WriteLine("Instance constructor");
}
~MyClass() {
    Console.WriteLine("Finalizer");
}
static MyClass() {
    MyStaticField *= 2;
    Console.WriteLine("Static constructor");
}
internal class MyNestedClass
{}
}
```

shows a class that contains each kind of member. The example

class Test
{
    static void Main() {
        // Instance constructor usage
        MyClass a = new MyClass();
        MyClass b = new MyClass(123);
        // Constant usage
        Console.WriteLine("MyConst = {0}", MyClass.MyConst);
        // Field usage
        a.MyField++;
        Console.WriteLine("a.MyField = {0}", a.MyField);
        // Method usage
        a.MyMethod();
        // Property usage
        a.MyProperty++;
        Console.WriteLine("a.MyProperty = {0}", a.MyProperty);
        // Indexer usage
        Console.WriteLine("a[3] = {0}", a[3]);
        // Event usage
        a.MyEvent += new EventHandler(MyHandler);
        // Overloaded operator usage
        MyClass c = a + b;
    }
}

8.7.1 Constants

A **constant** is a class member that represents a constant value: a value that can be computed at compile-time. Constants are permitted to depend on other constants within the same program as long as there are no circular dependencies. The rules governing constant expressions are defined in §14.16. The example

```csharp
class Constants
{
    public const int A = 1;
    public const int B = A + 1;
}
```

shows a class named **Constants** that has two public constants.

Even though constants are considered static members, a constant declaration neither requires nor allows the modifier **static**. Constants can be accessed through the class, as in

```csharp
using System;
class Test
{
    static void Main() {
        Console.WriteLine("{0}, {1}", Constants.A, Constants.B);
    }
}
```

which prints out the values of **Constants.A** and **Constants.B**, respectively.

8.7.2 Fields

A **field** is a member that represents a variable associated with an object or class. The example

```csharp
class Color
{
    internal ushort redPart;
    internal ushort bluePart;
    internal ushort greenPart;
    public Color(ushort red, ushort blue, ushort green) {
        redPart = red;
        bluePart = blue;
        greenPart = green;
    }
    public static Color Red = new Color(0xFF, 0, 0);
    public static Color Blue = new Color(0, 0xFF, 0);
    public static Color Green = new Color(0, 0, 0xFF);
    public static Color White = new Color(0xFF, 0xFF, 0xFF);
}
```

shows a **Color** class that has internal instance fields named **redPart**, **bluePart**, and **greenPart**, and static fields named **Red**, **Blue**, **Green**, and **White**.

The use of static fields in this manner is not ideal. The fields are initialized at some point before they are used, but after this initialization, there is nothing to stop a client from changing them. Such a modification could cause unpredictable errors in other programs that use **Color** and assume that the values do not change. **Readonly fields** can be used to prevent such problems. Assignments to a readonly field can only occur as part of the declaration, or in an instance constructor or static constructor in the same class. A static readonly field can be assigned in a static constructor, and a non-static readonly field can be assigned in an
instance constructor. Thus, the Color class can be enhanced by adding the modifier readonly to the static fields:

```csharp
class Color
{
    internal ushort redPart;
    internal ushort bluePart;
    internal ushort greenPart;
    public Color(ushort red, ushort blue, ushort green) {
        redPart = red;
        bluePart = blue;
        greenPart = green;
    }
    public static readonly Color Red = new Color(0xFF, 0, 0);
    public static readonly Color Blue = new Color(0, 0xFF, 0);
    public static readonly Color Green = new Color(0, 0, 0xFF);
    public static readonly Color White = new Color(0xFF, 0xFF, 0xFF);
}
```

8.7.3 Methods

A method is a member that implements a computation or action that can be performed by an object or class. Methods have a (possibly empty) list of formal parameters, a return value (unless the method's return-type is void), and are either static or non-static. Static methods are accessed through the class. Non-static methods, which are also called instance methods, are accessed through instances of the class. A generic method (§25.6) has a list of one or more type parameters. The example

```csharp
using System;
public class Stack
{
    public static Stack Clone(Stack s) { ... }
    public static Stack Flip(Stack s) { ... }
    public object Pop() { ... }
    public void Push(object o) { ... }
    public void PushMultiple<T>(T[] a) { ... }
    public override string ToString() { ... }
}

class Test
{
    static void Main()
    {
        Stack s = new Stack();
        for (int i = 1; i < 10; i++)
            s.Push(i);
        Stack flipped = Stack.Flip(s);
        Stack cloned = Stack.Clone(s);
        Console.WriteLine("Original stack: " + s.ToString());
        Console.WriteLine("Flipped stack: " + flipped.ToString());
        Console.WriteLine("Cloned stack: " + cloned.ToString());
    }
}
```

shows a Stack that has several static methods (Clone and Flip) and several instance methods (Pop, Push, and ToString) and a generic method (PushMultiple<T>).

Methods can be overloaded, which means that multiple methods can have the same name so long as they have unique signatures. The signature of a method consists of the name of the method and the number, modifiers, and types of its formal parameters, and the number of generic type parameters. The signature of a method does not include the return type or the names of the formal parameters or type parameters. The example
using System;

class Test
{
    static void F() {
        Console.WriteLine("F()");  
    }
    static void F(object o) {
        Console.WriteLine("F(object)");  
    }
    static void F(int value) {
        Console.WriteLine("F(int)");  
    }
    static void F(ref int value) {
        Console.WriteLine("F(ref int)");  
    }
    static void F(int a, int b) {
        Console.WriteLine("F(int, int)");  
    }
    static void F(int[] values) {
        Console.WriteLine("F(int[])");  
    }
    static void F<T>(T t) {
        Console.WriteLine("F<T>(T)");  
    }
    static void Main() {
        F();
        F(1);
        int i = 10;
        F(ref i);
        F((object)1);
        F(1, 2);
        F(new int[] {1, 2, 3});
        F("Hello");
        F("World");
    }
}

shows a class with a number of methods called F. The output produced is

F()
F(int)
F(ref int)
F(object)
F(int, int)
F(int[])
F<T>(T)
F<string>("world")

8.7.4 Properties

A property is a member that provides access to a characteristic of an object or a class. Examples of properties include the length of a string, the size of a font, the caption of a window, the name of a customer, and so on. Properties are a natural extension of fields. Both are named members with associated types, and the syntax for accessing fields and properties is the same. However, unlike fields, properties do not denote storage locations. Instead, properties have accessors that specify the statements to be executed when their values are read or written.

Properties are defined with property declarations. The first part of a property declaration looks quite similar to a field declaration. The second part includes a get accessor and/or a set accessor. In the example below, the Button class defines a Caption property.
Properties that can be both read and written, such as `Caption`, include both get and set accessors. The get accessor is called when the property’s value is read; the set accessor is called when the property’s value is written. In a set accessor, the new value for the property is made available via an implicit parameter named `value`.

The declaration of properties is relatively straightforward, but the real value of properties is seen when they are used. For example, the `Caption` property can be read and written in the same way that fields can be read and written:

```csharp
Button b = new Button();
b.Caption = "ABC";  // set; causes repaint
string s = b.Caption; // get
b.Caption += "DEF";  // get & set; causes repaint
```

### 8.7.5 Events

An **event** is a member that enables an object or class to provide notifications. A class defines an event by providing an event declaration (which resembles a field declaration, though with an added `event` keyword) and an optional set of event accessors. The type of this declaration shall be a delegate type.

An instance of a delegate type encapsulates one or more callable entities. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Given a delegate instance and an appropriate set of arguments, one can invoke all of that delegate instance’s methods with that set of arguments.

In the example

```csharp
public delegate void EventHandler(object sender, System.EventArgs e);
public class Button
{
    public event EventHandler Click;
    public void Reset() {
        Click = null;
    }
}
```

the `Button` class defines a `Click` event of type `EventHandler`. Inside the `Button` class, the `Click` member is exactly like a private field of type `EventHandler`. However, outside the `Button` class, the `Click` member can only be used on the left-hand side of the `+=` and `-=` operators. The `+=` operator adds a handler for the event, and the `-=` operator removes a handler for the event. The example

```csharp
using System;
public class Form1
{
    public Form1() {
        // Add Button1_Click as an event handler for Button1's Click event
        Button1.Click += new EventHandler(Button1_Click);
    }

    Button Button1 = new Button();
}
```
void Button1_Click(object sender, EventArgs e) {
    Console.WriteLine("Button1 was clicked!");
}

public void Disconnect() {
    Button1.Click -= new EventHandler(Button1_Click);
}

shows a Form1 class that adds Button1_Click as an event handler for Button1’s Click event. In the Disconnect method, that event handler is removed.

For a simple event declaration such as

    public event EventHandler click;

the compiler automatically provides the implementation underlying the += and -= operators.

An implementer who wants more control can get it by explicitly providing add and remove accessors. For example, the Button class could be rewritten as follows:

    public class Button
    {
        private EventHandler handler;
        public event EventHandler Click {
            add { handler += value; }
            remove { handler -= value; }
        }
    }

This change has no effect on client code, but allows the Button class more implementation flexibility. For example, the event handler for Click need not be represented by a field.

8.7.6 Operators

An operator is a member that defines the meaning of an expression operator that can be applied to instances of the class. Three kinds of operators can be defined: unary, binary, and conversion.

The following example defines a Digit type that represents decimal digits—integral values between 0 and 9.

    using System;
    public struct Digit
    {
        byte value;
        public Digit(int value) {
            if (value < 0 || value > 9) throw new ArgumentException();
            this.value = (byte)value;
        }
        public static implicit operator byte(Digit d) {
            return d.value;
        }
        public static explicit operator Digit(int value) {
            return new Digit(value);
        }
        public static Digit operator+(Digit a, Digit b) {
            return new Digit(a.value + b.value);
        }
        public static Digit operator-(Digit a, Digit b) {
            return new Digit(a.value - b.value);
        }
        public static bool operator==(Digit a, Digit b) {
            return a.value == b.value;
        }
    }
The `Digit` type defines the following operators:

- An implicit conversion operator from `Digit` to `byte`.
- An explicit conversion operator from `int` to `Digit`.
- An addition operator that adds two `Digit` values and returns a `Digit` value.
- A subtraction operator that subtracts one `Digit` value from another, and returns a `Digit` value.
- The equality (==) and inequality (!=) operators, which compare two `Digit` values.

### 8.7.7 Indexers

An *indexer* is a member that enables an object to be indexed in the same way as an array. Whereas properties enable field-like access, indexers enable array-like access.

As an example, consider the `Stack` class presented earlier. The designer of this class might want to expose array-like access so that it is possible to inspect or alter the items on the stack without performing unnecessary `Push` and `Pop` operations. That is, class `Stack` is implemented as a linked list, but it also provides the convenience of array access.

Indexer declarations are similar to property declarations, with the main differences being that indexers are nameless (the “name” used in the declaration is `this`, since `this` is being indexed) and that indexers include indexing parameters. The indexing parameters are provided between square brackets. The example

```csharp
using System;
```
public class Stack
{
    private Node GetNode(int index) {
        Node temp = first;
        while (true) {
            if (temp == null || index < 0)
                throw new Exception("Index out of range.");
            if (index == 0)
                return temp;
            temp = temp.Next;
            index--;
        }
    }
    public object this[int index] {
        get {
            return GetNode(index).Value;
        }
        set {
            GetNode(index).Value = value;
        }
    }
    ...
}
class Test
{
    static void Main() {
        Stack s = new Stack();
        s.Push(1);
        s.Push(2);
        s.Push(3);
        s[0] = 33; // Changes the top item from 3 to 33
        s[1] = 22; // Changes the middle item from 2 to 22
        s[2] = 11; // Changes the bottom item from 1 to 11
    }
}

shows an indexer for the Stack class.

8.7.8 Instance constructors

An instance constructor is a member that implements the actions required to initialize an instance of a class.

The example

using System;
class Point
{
    public double x, y;
    public Point() {
        this.x = 0;
        this.y = 0;
    }
    public Point(double x, double y) {
        this.x = x;
        this.y = y;
    }
    public static double Distance(Point a, Point b) {
        double xdiff = a.x - b.x;
        double ydiff = a.y - b.y;
        return Math.Sqrt(xdiff * xdiff + ydiff * ydiff);
    }
}
public override string ToString() {
    return string.Format("({0}, {1})", x, y);
}
}
class Test
{
    static void Main()
    {
        Point a = new Point();
        Point b = new Point(3, 4);
        double d = Point.Distance(a, b);
        Console.WriteLine("Distance from {0} to {1} is {2}", a, b, d);
    }
}

shows a Point class that provides two public instance constructors, one of which takes no arguments, while the other takes two double arguments.

If no instance constructor is supplied for a class, then one having no parameters is automatically provided, which simply invokes the parameterless constructor of the direct base class.

8.7.9 Finalizers

A finalizer is a member that implements the actions required to finalize an instance of a class. Finalizers cannot have parameters, they cannot have accessibility modifiers, and they cannot be called explicitly. The finalizer for an instance is called automatically during garbage collection.

The example

```csharp
using System;
class Point
{
    public double x, y;
    public Point(double x, double y) {
        this.x = x;
        this.y = y;
    }
    ~Point() {
        Console.WriteLine("Finalized {0}", this);
    }
    public override string ToString() {
        return string.Format("({0}, {1})", x, y);
    }
}
```

shows a Point class with a finalizer.

8.7.10 Static constructors

A static constructor is a member that implements the actions required to initialize a class. Static constructors cannot have parameters, they cannot have accessibility modifiers, and they cannot be called explicitly. The static constructor for a class is called automatically.

The example

```csharp
using Personnel.Data;
class Employee
{
    private static DataSet ds;
    static Employee() {
        ds = new DataSet(...);
    }
```
public string Name;
public decimal Salary;

shows an Employee class with a static constructor that initializes a static field.

### 8.7.11 Inheritance

Classes support single inheritance, and the type object is the ultimate base class for all classes. The classes shown in earlier examples all implicitly derive from object. The example

```csharp
using System;
class A
{
    public void F() { Console.WriteLine("A.F"); }
}
```

shows a class A that implicitly derives from object. The example

```csharp
class B: A
{
    public void G() { Console.WriteLine("B.G"); }
}
class Test
{
    static void Main()
    {
        B b = new B();
        b.F(); // Inherited from A
        b.G(); // Introduced in B

        A a = b; // Treat a B as an A
        a.F();
    }
}
```

shows a class B that derives from A. The class B inherits A’s F method, and introduces a G method of its own.

Methods, properties, and indexers can be virtual, which means that their implementation can be overridden in derived classes. The example

```csharp
using System;
class A
{
    public virtual void F() { Console.WriteLine("A.F"); }
}
class B: A
{
    public override void F()
    {
        base.F();
        Console.WriteLine("B.F");
    }
}
class Test
{
    static void Main()
    {
        B b = new B();
        b.F();

        A a = b;
        a.F();
    }
}
```

shows a class A with a virtual method F, and a class B that overrides F. The overriding method in B contains a call, base.F(), which calls the overridden method in A.
A class can indicate that it is incomplete, and is intended only as a base class for other classes, by including the modifier \texttt{abstract}. Such a class is called an \texttt{abstract class}. An abstract class can specify \texttt{abstract members}—members that a non-abstract derived class shall implement. The example

\begin{verbatim}
using System;
abstract class A
{
    public abstract void F();
}
class B: A
{
    public override void F() { Console.WriteLine("B.F"); }
}
class Test
{
    static void Main()
    {
        B b = new B();
        b.F();
        A a = b;
        a.F();
    }
}
\end{verbatim}

introduces an abstract method \texttt{F} in the abstract class \texttt{A}. The non-abstract class \texttt{B} provides an implementation for this method.

\subsection{8.7.12 Static classes}

Classes that are not intended to be instantiated, and which contain only static members should be declared as static classes. Examples of such classes are \texttt{System.Console} and \texttt{System.Environment}. Static classes are implicitly sealed and have no instance constructors. Static classes can be used only with the typeof operator and to access elements of the class. In particular, a static class cannot be used as the type of a variable or be used as a type argument.

\begin{verbatim}
public static class Months
{
    static Months() { ... }
    private static readonly string[] monthName = { ... }
    public static string GetMonthName(int mm) { ... }
    private static readonly int[,] daysInMonth = { ... }
    public static int GetDaysInMonth(bool isLeapYear, int mm) { ... }
    public static bool IsLeapYear(int yy) { ... }
}
\end{verbatim}

\subsection{8.7.13 Partial type declarations}

In certain situations, the declaration of a type may grow so large that keeping it in a single source file becomes impractical or difficult. In such cases, it is often desirable to split that class declaration into multiple source files, with each source file focusing on one or more semi-independent concerns.

Another common situation occurs when code is generated from a program rather than written by a person. In rich frameworks and development environments, it is often most efficient to have parts of a project’s source code generated automatically from visual form designers, database schemas, RPC descriptions, etc. While these kinds of tools produce huge productivity gains, they suffer from problems when we wish to customize the output, possibly by adding members to generated classes. If we directly modify the output of the code generator, then those changes will be lost if the code generator needs to be run again. By placing the customized additions in a different source file, lost modifications can be greatly reduced or eliminated.

Partial type declarations allow greater flexibility in these situations by allowing the definition of a class, struct, or interface to be split into as many different pieces as needed. For example, when the following source files are compiled together:
// machine-generated code in file #1
partial class Widget
{
    private int[] counts;
    public string ToString() {
        ...
    }
}

// programmer-generated code in file #2
partial class Widget
{
    private int value;
    private void Helper() {
        // ...
    }
    public int Process(object obj) {
        ...
    }
}

Widget's members are the union of all the members in all its parts.

8.8 Structs

The list of similarities between classes and structs is long—structs can implement interfaces, and can have
the same kinds of members as classes. Structs differ from classes in several important ways, however:
structs are value types rather than reference types, and inheritance is not supported for structs. Struct values
are stored "on the stack" or "in-line". Careful programmers can sometimes enhance performance through
judicious use of structs.

For example, the use of a struct rather than a class for a Point can make a large difference in the number of
memory allocations performed at run time. The program below creates and initializes an array of 100 points.
With Point implemented as a class, 101 separate objects are instantiated—one for the array and one each
for the 100 elements.

class Point
{
    public int x, y;
    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
class Test
{
    static void Main() {
        Point[] points = new Point[100];
        for (int i = 0; i < 100; i++)
            points[i] = new Point(i, i*i);
    }
}

If Point is instead implemented as a struct, as in

struct Point
{
    public int x, y;
    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}

only one object is instantiated—the one for the array. The Point instances are allocated in-line within the
array. This optimization can be misused. Using structs instead of classes can also make an application run
slower or take up more memory, as passing a struct instance by value causes a copy of that struct to be created.

### 8.9 Interfaces

An interface defines a contract. A class or struct that implements an interface shall adhere to its contract. Interfaces can contain methods, properties, events, and indexers as members.

The example

```csharp
interface IExample
{
    string this[int index] { get; set; }
    event EventHandler E;
    void F(int value);
    string P { get; set; }
}

public delegate void EventHandler(object sender, EventArgs e);
```

shows an interface that contains an indexer, an event E, a method F, and a property P.

Interfaces can employ multiple inheritance. In the example

```csharp
interface IControl
{
    void Paint();
}

interface ITextBox: IControl
{
    void SetText(string text);
}

interface IListBox: IControl
{
    void SetItems(string[] items);
}

interface IComboBox: ITextBox, IListBox {}
```

the interface IComboBox inherits from both ITextBox and IListBox.

Classes and structs can implement multiple interfaces. In the example

```csharp
interface IDataBound
{
    void Bind(Binder b);
}

public class EditBox: Control, IControl, IDataBound
{
    public void Paint() {…}
    public void Bind(Binder b) {…}
}
```

the class EditBox derives from the class Control and implements both IControl and IDataBound.

In the previous example, the Paint method from the IControl interface and the Bind method from IDataBound interface are implemented using public members on the EditBox class. C# provides an alternative way of implementing these methods that allows the implementing class to avoid having these members be public. Interface members can be implemented using a qualified name. For example, the EditBox class could instead be implemented by providing IControl.Paint and IDataBound.Bind methods.

```csharp
public class EditBox: IControl, IDataBound
{
    void IControl.Paint() {…}
    void IDataBound.Bind(Binder b) {…}
}
```
Interface members implemented in this way are called **explicit interface members** because each member explicitly designates the interface member being implemented. Explicit interface members can only be called via the interface. For example, the EditBox’s implementation of the Paint method can be called only by casting to the IControl interface.

```csharp
class Test
{
    static void Main() {
        EditBox editbox = new EditBox();
        editbox.Paint(); // error: no such method
        IControl control = editbox;
        control.Paint(); // calls EditBox’s Paint implementation
    }
}
```

# 8.10 Delegates

Delegates enable scenarios that some other languages have addressed with function pointers. However, unlike function pointers, delegates are object-oriented and type-safe.

A delegate declaration defines a class that is derived from the class System.Delegate. A delegate instance encapsulates one or more methods, each of which is referred to as a **callable entity**. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Given a delegate instance and an appropriate set of arguments, one can invoke all of that delegate instance’s methods with that set of arguments.

An interesting and useful property of a delegate instance is that it does not know or care about the classes of the methods it encapsulates; all that matters is that those methods be consistent (§22.1) with the delegate’s type. This makes delegates perfectly suited for “anonymous” invocation. This is a powerful capability.

There are three steps in defining and using delegates: declaration, instantiation, and invocation. Delegates are declared using delegate declaration syntax. The example

```csharp
delegate void SimpleDelegate();
```

declares a delegate named SimpleDelegate that takes no arguments and returns no result.

The example

```csharp
class Test
{
    static void F() {
        System.Console.WriteLine("Test.F");
    }
    static void Main() {
        SimpleDelegate d = new SimpleDelegate(F);
        d();
    }
}
```

creates a SimpleDelegate instance and then immediately calls it.

There is not much point in instantiating a delegate for a method and then immediately calling that method via the delegate, as it would be simpler to call the method directly. Delegates really show their usefulness when their anonymity is used. The example

```csharp
void MultiCall(SimpleDelegate d, int count) {
    for (int i = 0; i < count; i++) {
        d();
    }
}
```

shows a MultiCall method that repeatedly calls a SimpleDelegate. The MultiCall method doesn’t know or care about the type of the target method for the SimpleDelegate, what accessibility that method has, or whether or not that method is static. All that matters is that the target method is consistent (§22.1) with SimpleDelegate.
### 8.11 Enums

An enum type declaration defines a type name for a related group of symbolic constants. Enums are used for "multiple choice" scenarios, in which a runtime decision is made from a fixed number of choices that are known at compile-time.

The example

```csharp
enum Color
{
    Red,
    Blue,
    Green
}

class Shape
{
    public void Fill(Color color) {
        switch(color) {
            case Color.Red:
                ...
                break;
            case Color.Blue:
                ...
                break;
            case Color.Green:
                ...
                break;
            default:
                break;
        }
    }
}
```

shows a `Color` enum and a method that uses this enum. The signature of the `Fill` method makes it clear that the shape can be filled with one of the given colors.

The use of enums is superior to the use of integer constants—as is common in languages without enums—because the use of enums makes the code more readable and self-documenting. The self-documenting nature of the code also makes it possible for the development tool to assist with code writing and other "designer" activities. For example, the use of `Color` rather than `int` for a parameter type enables smart code editors to suggest `Color` values.

### 8.12 Namespaces and assemblies

The programs presented so far have stood on their own except for dependence on a few system-provided classes such as `System.Console`. It is far more common, however, for real-world applications to consist of several different pieces, each compiled separately. For example, a corporate application might depend on several different components, including some developed internally and some purchased from independent software vendors.

Namespaces and assemblies enable this component-based system. Namespaces provide a logical organizational system. Namespaces are used both as an "internal" organization system for a program, and as an "external" organization system—a way of presenting program elements that are exposed to other programs.

Assemblies are used for physical packaging and deployment. An assembly can contain types, the executable code used to implement these types, and references to other assemblies.

To demonstrate the use of namespaces and assemblies, this subclause revisits the "hello, world" program presented earlier, and splits it into two pieces: a class library that provides messages and a console application that displays them.

The class library will contain a single class named `HelloMessage`. The example
shows the **HelloMessage** class in a namespace named `CSharp.Introduction`. The **HelloMessage** class provides a read-only property named **Message**. Namespaces can nest, and the declaration

```csharp
namespace CSharp.Introduction
{
    public class HelloMessage
    {
        public string Message {
            get {
                return "hello, world";
            }
        }
    }
}
```

shows a using namespace directive that refers to the `CSharp.Introduction` namespace. The occurrences of **HelloMessage** are shorthand for `CSharp.Introduction.HelloMessage`.

C# also enables the definition and use of aliases. A **using alias directive** defines an alias for a type or namespace. Such aliases can be useful in situations in which name collisions occur between two class libraries, or when a small number of types from a much larger namespace are being used. The example

```csharp
using MessageSource = CSharp.Introduction.HelloMessage;
```

shows a using alias directive that defines **MessageSource** as an alias for the **HelloMessage** class.

The code we have written can be compiled into a class library containing the class **HelloMessage** and an application containing the class **HelloApp**. The details of this compilation step might differ based on the compiler or tool being used. A command-line compiler might enable compilation of a class library and an application that uses that library with the following command-line invocations:

```bash
csc /target:library HelloLibrary.cs

csc /reference:HelloLibrary.dll HelloApp.cs
```

describe which produce a class library named **HelloLibrary.dll** and an application named **HelloApp.exe**.
8.13 Versioning

Versioning is the process of evolving a component over time in a compatible manner. A new version of a component is source compatible with a previous version if code that depends on the previous version can, when recompiled, work with the new version. In contrast, a new version of a component is binary-compatible if an application that depended on the old version can, without recompilation, work with the new version.

Most languages do not support binary compatibility at all, and many do little to facilitate source compatibility. In fact, some languages contain flaws that make it impossible, in general, to evolve a class over time without breaking at least some client code.

As an example, consider the situation of a base class author who ships a class named `Base`. In the first version, `Base` contains no method `F`. A component named `Derived` derives from `Base`, and introduces an `F`. This `Derived` class, along with the class `Base` on which it depends, is released to customers, who deploy to numerous clients and servers.

```csharp
// Author A
namespace A
{
    public class Base  // version 1
    {
    }
}
// Author B
namespace B
{
    class Derived: A.Base
    {
        public virtual void F() {
            System.Console.WriteLine("Derived.F");
        }
    }
}
```

So far, so good, but now the versioning trouble begins. The author of `Base` produces a new version, giving it its own method `F`.

```csharp
// Author A
namespace A
{
    public class Base  // version 2
    {
        public virtual void F() {  // added in version 2
            System.Console.WriteLine("Base.F");
        }
    }
}
```

This new version of `Base` should be both source and binary compatible with the initial version. (If it weren’t possible to simply add a method then a base class could never evolve.) Unfortunately, the new `F` in `Base` makes the meaning of `Derived`’s `F` unclear. Did `Derived` mean to override `Base`’s `F`? This seems unlikely, since when `Derived` was compiled, `Base` did not even have an `F`! Further, if `Derived`’s `F` does override `Base`’s `F`, then it shall adhere to the contract specified by `Base`—a contract that was unspecified when `Derived` was written. In some cases, this is impossible. For example, `Base`’s `F` might require that overrides of it always call the base. `Derived`’s `F` could not possibly adhere to such a contract.

C# addresses this versioning problem by requiring developers to state their intent clearly. In the original code example, the code was clear, since `Base` did not even have an `F`. Clearly, `Derived`’s `F` is intended as a new method rather than an override of a base method, since no base method named `F` exists.

If `Base` adds an `F` and ships a new version, then the intent of a binary version of `Derived` is still clear—`Derived`’s `F` is semantically unrelated, and should not be treated as an override.
However, when Derived is recompiled, the meaning is unclear—the author of Derived might intend its F to override Base’s F, or to hide it. Since the intent is unclear, the compiler produces a warning, and by default makes Derived’s F hide Base’s F. This course of action duplicates the semantics for the case in which Derived is not recompiled. The warning that is generated alerts Derived’s author to the presence of the F method in Base.

If Derived’s F is semantically unrelated to Base’s F, then Derived’s author can express this intent—and, in effect, turn off the warning—by using the new keyword in the declaration of F.

```
// Author A
namespace A
{
    public class Base   // version 2
    {
        public virtual void F() { // added in version 2
            System.Console.WriteLine("Base.F");
        }
    }
}
// Author B
namespace B
{
    class Derived: A.Base // version 2a: new
    {
        new public virtual void F() {
            System.Console.WriteLine("Derived.F");
        }
    }
}
```

On the other hand, Derived’s author might investigate further, and decide that Derived’s F should override Base’s F. This intent can be specified by using the override keyword, as shown below.

```
// Author A
namespace A
{
    public class Base     // version 2
    {
        public virtual void F() { // added in version 2
            System.Console.WriteLine("Base.F");
        }
    }
}
// Author B
namespace B
{
    class Derived: A.Base // version 2b: override
    {
        public override void F() {
            base.F();
            System.Console.WriteLine("Derived.F");
        }
    }
}
```

The author of Derived has one other option, and that is to change the name of F, thus completely avoiding the name collision. Although this change would break source and binary compatibility for Derived, the importance of this compatibility varies depending on the scenario. If Derived is not exposed to other programs, then changing the name of F is likely a good idea, as it would improve the readability of the program—there would no longer be any confusion about the meaning of F.

### 8.14 Extern aliases

By default types from all referenced assemblies and the current program are placed into a single namespace hierarchy. With only a single namespace hierarchy, it is not possible to reference types with the same fully
qualified name from different assemblies, a situation that arises when types are independently given the same name, or when a program needs to reference several versions of the same assembly. *Extern aliases* make it possible to create and reference separate namespace hierarchies in such situations.

Consider the following two assemblies:

```csharp
// Assembly a1.dll:
namespace N
{
    public class A {}
    public class B {}
}

// Assembly a2.dll:
namespace N
{
    public class B {}
    public class C {}
}
```

and the following program:

```csharp
class Test
{
    N.A a;   // Ok
    N.B b;   // Error
    N.C c;   // Ok
}
```

A command-line compiler might allow compilation of this program with a command-line something like this:

```
csc /r:a1.dll /r:a2.dll test.cs
```

where the types contained in `a1.dll` and `a2.dll` are all placed in the global namespace hierarchy, and an error occurs because the type `N.B` exists in both assemblies. With extern aliases, it becomes possible to place the types contained in `a1.dll` and `a2.dll` into separate namespace hierarchies.

The following program declares and uses two extern aliases, X and Y, each of which represent the root of a distinct namespace hierarchy created from the types contained in one or more assemblies.

```csharp
extern alias X;
extern alias Y;
class Test
{
    X::N.A a;           // Ok
    X::N.B b1;          // Error
    Y::N.B b2;
    Y::N.C c;
}
```

A command-line compiler might allow compilation of this program with a command-line something like this:

```
csc /r:X=a1.dll /r:Y=a2.dll test.cs
```

where the types contained in `a1.dll` and `a2.dll` are all placed in the global namespace hierarchy, and an error occurs because the type `N.B` exists in both assemblies. With extern aliases, it becomes possible to place the types contained in `a1.dll` and `a2.dll` into separate namespace hierarchies.

The following program declares and uses two extern aliases, X and Y, each of which represent the root of a distinct namespace hierarchy created from the types contained in one or more assemblies.

```csharp
extern alias X;
extern alias Y;
class Test
{
    X::N.A a;           // Ok
    X::N.B b1;          // Error
    Y::N.B b2;
    Y::N.C c;
}
```

The program declares the existence of the extern aliases X and Y, but the actual definitions of the aliases are external to the program. A command line compiler can enable the definition of the extern aliases X and Y such that the extern alias X is the root of a namespace hierarchy formed by the types in `a1.dll` and Y is the root of a namespace hierarchy formed by the types in `a2.dll`. A compiler might enable the above example with a command-line like:

```
csc /r:X=a1.dll /r:Y=a2.dll test.cs
```

The identically named `N.B` classes can now be referenced as `X.N.B` and `Y.N.B`, or, using the namespace alias qualifier, `X::N.B` and `Y::N.B`. An error occurs if a program declares an extern alias for which no external definition is provided.

An extern alias can include multiple assemblies, and a particular assembly can be included in multiple extern aliases. For example, given the assembly
// Assembly a3.dll:

namespace N {
    public class D {}
    public class E {}
}

A command line like

might define the extern alias X to be the root of a namespace hierarchy formed by the types in a1.dll and a3.dll and Y to be the root of a namespace hierarchy formed by the types in a2.dll and a3.dll. Because of this definition, it is possible to refer to the class N.D in a3.dll as both X::N.D and Y::N.D.

An assembly can be placed in the global namespace hierarchy even if it is also included in one or more extern aliases. For example, the command line

csc /r:a1.dll /r:X=a1.dll /r:Y=a2.dll test.cs

places the assembly a1.dll in both the global namespace hierarchy and the namespace hierarchy rooted by the extern alias X. Consequently, the class N.A can be referred to as N.A or X::N.A.

It is possible to ensure that a lookup always starts at the root of the global namespace hierarchy by using the identifier global with the namespace alias qualifier, such as global::System.IO.Stream.

A using directive may reference an extern alias that was defined in the same immediately enclosing namespace declaration or compilation unit. For example:

extern alias X;
using X::N;

class Test {
    A a;  // X::N.A
    B b;  // X::N.B
}

8.15 Attributes

C# is an imperative language, but like all imperative languages, it does have some declarative elements. For example, the accessibility of a method in a class is specified by declaring it public, protected, internal, protected internal, or private. C# generalizes this capability, so that programmers can invent new kinds of declarative information, attach this declarative information to various program entities, and retrieve this declarative information at run-time. Programs specify this additional declarative information by defining and using attributes (§24).

For instance, a framework might define a HelpAttribute attribute that can be placed on program elements such as classes and methods, enabling developers to provide a mapping from program elements to documentation for them. The example

using System;

[AttributeUsage(AttributeTargets.All)]
public class HelpAttribute : Attribute {
    public HelpAttribute(string url) {
        this.url = url;
    }
    public string Topic = null;
    private string url;
    public string Url {
        get { return url; }
    }
    }
}
defines an attribute class named `HelpAttribute`, or `Help` for short, that has one positional parameter (`string url`) and one named parameter (`string Topic`). Positional parameters are defined by the formal parameters for public instance constructors of the attribute class, and named parameters are defined by public non-static read-write fields and properties of the attribute class.

The example

```csharp
[Help("http://www.mycompany.com/.../Class1.htm")]
public class Class1
{
    [Help("http://www.mycompany.com/.../Class1.htm", Topic = "F")]
    public void F() {}
}
```

shows several uses of the attribute `Help`.

Attribute information for a given program element can be retrieved at run-time by using reflection support. The example

```csharp
using System;

class Test
{
    static void Main()
    {
        Type type = typeof(Class1);
        object[] arr = type.GetCustomAttributes(
            typeof(HelpAttribute), true);
        if (arr.Length == 0)
        {
            Console.WriteLine("Class1 has no Help attribute.");
        }
        else
        {
            HelpAttribute ha = (HelpAttribute) arr[0];
            Console.WriteLine("Url = {0}, Topic = {1}", ha.Url, ha.Topic);
        }
    }
}
```

checks to see if `Class1` has a `Help` attribute, and writes out the associated `Url` and `Topic` values if the attribute is present.

### 8.16 Generics

C# allows classes, structs, interfaces, and methods to be parameterized by the types of data they store and manipulate. This feature is really a set of features known collectively as **generics**. C# generics will immediately be familiar to users of generics in Eiffel or Ada, or to users of templates in C++.

Many common classes and structs can be parameterized by the types of data being stored and manipulated—these are called **generic class declarations** and **generic struct declarations**, respectively. Similarly, many interfaces define contracts that can be parameterized by the types of data they handle—these are called **generic interface declarations**. In order to implement “generic algorithms,” methods can also be parameterized by type; such methods are known as **generic methods**.

#### 8.16.1 Why generics?

Without generics, programmers can store data of any type in variables of the base type `object`. To illustrate, let’s create a simple `Stack` type with two actions, “Push” and “Pop”. The `Stack` class stores its data in an array of `object`, and the `Push` and `Pop` methods use the `object` type to accept and return data, respectively:

```csharp
public class Stack
{
    private object[] items = new object[100];
    public void Push(object data) {...}
    public object Pop() {...}
}
```

We can then push a value of any type, such as a `Customer` type, for example, onto the stack. However, when we wanted to retrieve that value, we would need to cast explicitly the result of the `Pop` method, an
object, into a Customer type, which is tedious to write, and carries a performance penalty for run-time type checking:

```java
Stack s = new Stack();
s.Push(new Customer());
Customer c = (Customer)s.Pop();
```

If we pass to the Push method a value type, such as an int, it will automatically be boxed. Similarly, if we want to retrieve an int from the stack, we would need to unbox explicitly the object type we obtain from the Pop method:

```java
Stack s = new Stack();
s.Push(3);
int i = (int)s.Pop();
```

Such boxing and unboxing operations can affect performance. Furthermore, in the implementation shown, it is not possible to enforce the kind of data placed in the stack. Indeed, we could create a stack and push a Customer type onto it. However, later, we could use the same stack and try to pop data off of it and cast it into an incompatible type:

```java
Stack s = new Stack();
s.Push(new Customer());
Employee e = (Employee)s.Pop(); // runtime error
```

While the code above is an improper use of the Stack class we presumably intended to implement, and should be a compile-time error, it is actually valid code. However, at run-time, the application will fail because we have performed an invalid cast operation.

### 8.16.2 Creating and consuming generics

Generics provide a facility for creating high-performance data structures that are specialized by the compiler and/or execution engine based on the types that they use. These so-called generic type declarations are created so that their internal algorithms remain the same, yet the types of their external interface and internal data can vary based on user preference.

In order to minimize the learning curve for developers, generics are used in much the same way as C++ templates. Programmers can create classes and structures just as they normally have, and by using the angle bracket notation (< and >) they can specify type parameters. When the generic class declaration is used, each type parameter shall be replaced by a type argument that the user of the class supplies.

In the example below, we create a Stack generic class declaration where we specify a type parameter, called ItemType, declared in angle brackets after the declaration. Rather than forcing conversions to and from object, instances of the generic Stack class will accept the type for which they are created and store data of that type without conversion. The type parameter ItemType acts as a placeholder until a runtime type is specified at use. Note that ItemType is used as the element type for the internal items array, the type for the parameter to the Push method, and the return type for the Pop method:

```java
public class Stack<ItemType>
{
    private ItemType[] items = new ItemType[100];
    public void Push(ItemType data) {...}
    public ItemType Pop() {...}
}
```

When we use the generic class declaration Stack, as in the short example below, we can specify the runtime type to be used by the generic class. In this case, we instruct the Stack to use an int type by specifying it as a type argument using the angle brackets after the name:

```java
Stack<int> s = new Stack<int>();
s.Push(3);
int x = s.Pop();
```

In so doing, we have created a new constructed type, Stack<int>, for which every ItemType inside the declaration of Stack is replaced with the supplied type argument int. Indeed, when we create our new instance of Stack<int>, the native storage of the items array is now an int[] rather than object[],
providing substantial storage efficiency. Additionally, we have eliminated the boxing penalty associated with pushing an int onto the stack. Further, when we pop an item off the stack, we no longer need to cast it explicitly to the appropriate type because this particular kind of Stack class natively stores an int in its data structure.

If we wanted to store items other than an int into a Stack, we would have to create a different constructed type from Stack, specifying a new type argument. Suppose we had a simple Customer type and we wanted to use a Stack to store it. To do so, we simply use the Customer class as the type argument to Stack and easily reuse our code:

```csharp
Stack<Customer> s = new Stack<Customer>();
s.Push(new Customer());
Customer c = s.Pop();
```

Of course, once we’ve created a Stack with a Customer type as its type argument, we are now limited to storing only Customer objects (or objects of a class derived from Customer). Generics provide strong typing, meaning we can no longer improperly store an integer into the stack, like so:

```csharp
Stack<Customer> s = new Stack<Customer>();
s.Push(new Customer());
s.Push(3);      // compile-time error
Customer c = s.Pop();  // no cast required
```

### 8.16.3 Multiple type parameters

Generic type declarations can have any number of type parameters. In our Stack example, we used only one type parameter. Suppose we created a simple Dictionary generic class declaration that stored values alongside keys. We could define a generic version of a Dictionary by declaring two type parameters, separated by commas within the angle brackets of the declaration:

```csharp
public class Dictionary<KeyType, ElementType>
{
    public void Add(KeyType key, ElementType val) {...}
    public ElementType this[KeyType key] {...}
}
```

When we use Dictionary, we need to supply two type arguments within the angle brackets. Then when we call the Add function or use the indexer, the compiler checks that we supplied the right types:

```csharp
Dictionary<string, Customer> dict = new Dictionary<string, Customer>();
dict.Add("Peter", new Customer());
Customer c = dict["Peter"];  // compile-time error
```

### 8.16.4 Constraints

In many cases, we will do more than store data based on a given type parameter. Often, we will also want to use members of the type parameter to execute statements within our generic type declaration.

For example, suppose in the Add method of our Dictionary we wanted to compare items using the CompareTo method of the supplied key, like so:

```csharp
public class Dictionary<KeyType, ElementType>
{
    public void Add(KeyType key, ElementType val)
    {
        ...
        if (key.CompareTo(x) < 0) {...} // compile-time error
    }
}
```

Unfortunately, at compile-time the type parameter KeyType is, as expected, generic. As written, the compiler will assume that only the operations available to object, such as ToString, are available on the variable key of type KeyType. As a result, the compiler will display an error because the CompareTo method would not be found. However, we can cast the key variable to a type that does contain a CompareTo method, such as an IComparable interface, allowing the program to compile:
public class Dictionary<KeyType, ElementType>
{
    public void Add(KeyType key, ElementType val)
    {
        if (((IComparable)key).CompareTo(x) < 0) {...}
    }
}

However, if we now construct a type from Dictionary and supply a type argument, which does not implement IComparable, we will encounter a run-time error, specifically an InvalidCastException. Since one of the objectives of generics is to provide strong typing and to reduce the need for casts, a more elegant solution is needed.

We can supply an optional list of constraints for each type parameter. A constraint indicates a requirement that a type shall fulfill in order to be accepted as a type argument. (For example, it might have to implement a given interface or be derived from a given base class.) A constraint is declared using the word where, followed by a type parameter and colon (:), followed by a comma-separated list of constraints, which can include a class type, interface types, other type parameters, the reference type constraint “class”, the value type constraint “struct”, and the constructor constraint “new()”.

In order to satisfy our need to use the CompareTo method inside Dictionary, we can impose a constraint on KeyType, requiring any type passed as the first argument to Dictionary to implement IComparable, like so:

public class Dictionary<KeyType, ElementType> where KeyType: IComparable
{
    public void Add(KeyType key, ElementType val)
    {
        if (key.CompareTo(x) < 0) {...}
    }
}

When compiled, this code will now be checked to ensure that each time we construct a Dictionary type we are passing a first type argument that implements IComparable. Further, we no longer have to cast variable key to IComparable explicitly before calling the CompareTo method.

Constraints are most useful when they are used in the context of defining a framework, i.e. a collection of related classes, where it is advantageous to ensure that a number of types support some common signatures and/or base types. Constraints can be used to help define “generic algorithms” that plug together functionality provided by different types. This can also be achieved by subclassing and runtime polymorphism, but static, constrained polymorphism can, in many cases, result in more efficient code, more flexible specifications of generic algorithms, and more errors being caught at compile-time rather than runtime. However, constraints need to be used with care and taste. Types that do not implement the constraints will not easily be usable in conjunction with generic code.

For any given type parameter, we can specify any number of interfaces and type parameters as constraints, but no more than one class. Each constrained type parameter has a separate where clause. In the example below, the KeyType type parameter has two interface constraints, while the ElementType type parameter has one class type constraint:

public class Dictionary<KeyType, ElementType >
    where KeyType: IComparable, IEnumerable
    where ElementType: Customer
{
    public void Add(KeyType key, ElementType val)
    {
    ...
8.16.5 Generic methods

In some cases, a type parameter is not needed for an entire class, but only when calling a particular method. Often, this occurs when creating a method that takes a generic type as a parameter. For example, when using the `Stack` described earlier, we might often find ourselves pushing multiple values in a row onto a stack, and decide to write a method to do so in a single call. If we are only using a single kind of `Stack`, say `Stack<int>`, writing such a method is easy:

```csharp
static void PushMultiple(Stack<int> s, params int[] values) {
    foreach (int v in values) {
        s.Push(v);
    }
}
```

We can use this method to push multiple `int` values onto a `Stack<int>`:

```csharp
Stack<int> s = new Stack<int>();
PushMultiple(s, 1, 2, 3, 4);
```

However, the method above only works with one particular constructed type: `Stack<int>`. While we can easily write similar code for other constructed `Stack` types, we would like to write a single method that can work with any `Stack`, no matter what type argument was used.

We do this by writing a **generic method**. Like a generic class declaration, a generic method is written with type parameters enclosed in angle brackets. With a generic method, the type parameters are written immediately after the method name, and can be used within the parameter list, return type, and body of the method. A generic `PushMultiple` method would look like this:

```csharp
static void PushMultiple<ItemType>(Stack<ItemType> s, params ItemType[] values) {
    foreach (ItemType v in values) {
        s.Push(v);
    }
}
```

Using this generic method, we can now push multiple items onto a `Stack` of any kind. Furthermore, the compiler type checking will ensure that the pushed items have the correct type for the kind of `Stack` being used. When calling a generic method, we place type arguments to the method in angle brackets. The generic `PushMultiple` method can be called this way:

```csharp
Stack<int> s = new Stack<int>();
PushMultiple<int>(s, 1, 2, 3, 4);
```

This generic `PushMultiple` method is much better than the previous version, since it works on any kind of `Stack`. However, it appears to be less convenient to call, since the desired `ItemType` shall be supplied as a type argument to the method. In many cases, however, the compiler can deduce the correct type argument from the other arguments passed to the method, using a process called **type inferencing**. In the example above, since the first regular argument is of type `Stack<int>`, and the subsequent arguments are of type `int`, the compiler can reason that the type parameter shall also be `int`. Thus, the generic `PushMultiple` method can be called without specifying the type parameter:

```csharp
Stack<int> s = new Stack<int>();
PushMultiple(s, 1, 2, 3, 4);
```

8.17 Anonymous methods

In C# code, a callback method is often invoked strictly through a delegate and not invoked directly. The purpose of such a method is obscured by the necessary separation of the method declaration from the delegate instantiation. In contrast, the body of an **anonymous method** is written “in-line” where the delegate is used, conveniently tying the method source code to the delegate instance. Besides this convenience,
An anonymous method has shared access to the local state of the containing function member. To achieve the same state sharing using named methods requires “lifting” local variables into fields of some object, further obscuring the source code.

An anonymous method is declared using an *anonymous-method-expression*:

```
debate anonymous-method-signatureopt block
```

The optional *anonymous-method-signature* defines the names and types of the formal parameters for the anonymous method. If the *anonymous-method-signature* is omitted, the *block* does not use any formal parameters. The *block* defines the body of the anonymous method.

An *anonymous-method-expression* is classified as a special kind of value that references the anonymous method. This value has no intrinsic type, but is implicitly convertible to any delegate type that has parameter types and a return type compatible with the anonymous method. If an anonymous method is declared without a signature, any delegate parameter types that do not include an *out* parameter are compatible with the anonymous method. If an anonymous method is declared with a signature, only delegate parameter types that exactly match in type and order are compatible. The return type of a delegate is compatible with an anonymous method if the expressions associated with all *return* statements in the anonymous method can be implicitly converted to the return type of the delegate. A *void* delegate return type is compatible with an anonymous method that has no *return* statements, or only has *return* statements with no expression.

Local variables and value parameters (including *this*) whose scope contains an anonymous method declaration are called *outer variables* of the anonymous method.

In the absence of anonymous methods, the lifetime of a local variable or value parameter ends when execution of its scope ends, as described in §12.1.7. However, an anonymous method can access an outer variable instance after execution has left the scope of the outer variable. In this case, the lifetime of the outer variable extends until all referencing anonymous method delegates are eligible for garbage collection, as described in §10.9.

An anonymous method cannot access *ref* or *out* parameters of an outer scope. The reason for this is that the caller of a function member allocates the storage for such parameters, so their lifetimes cannot be extended arbitrarily by the called function member. Consequently, since the *this* value of an instance method of a *struct* is equivalent to a *ref* parameter, an anonymous method in a *struct* is not allowed to access *this*.

Semantically, an anonymous method contained in a class or struct *T* is considered a method of *T*. If *T* is a class type, the anonymous method is considered an instance method or static method according to whether the containing function member is instance or static, respectively. In contrast, if *T* is a struct type, the anonymous method is always considered static and, as indicated above, cannot access *this*.

The following code defines an *Action* delegate type and a *Walk* method. The *Walk* method invokes an action sequentially on nodes in a linked list until either the action returns *false* or the end of the list is encountered.

```csharp
debate bool Action(Node n);
static void Walk(Node n, Action a) {
    while (n != null && a(n)) n = n.Next;
}
```

The following invocation of *Walk* employs an anonymous method to display the names of the nodes in a list:

```csharp
Walk(list,
    delegate(Node n) {
        Console.WriteLine(n.Name);
        return true;
    });
```
This code could easily be implemented using a named method, but doing so would require separating the method declaration from the invocation, obscuring the purpose of the method and the result of the invocation:

```csharp
class A
{
    int max;
    ...
    void F(Node list) {
        int c = 0;
        Walk(list,
            delegate(Node n) {
                if (c >= max) {
                    Console.WriteLine("... display truncated");
                    return false;
                }
                Console.WriteLine("{0}: {1}", ++c, n.Name);
                return true;
            });
        Console.WriteLine("Processed {0} nodes", c);
    }
    ...
}
```

Since `F` is an instance method of class `A`, the anonymous method is considered to be an instance method of `A`, and the field `max` is accessed through the anonymous method’s `this` variable (which is the same as `F`’s `this` variable). That is, `max` is a field, not an outer variable, and the anonymous method can access `max` just as any other instance method does.

Implementing this example in a safe way (considering the possibility of concurrency) without an anonymous method requires a significant amount of work and decreases clarity:

```csharp
class A
{
    int max;
    ...
    void F(Node list) {
        NodeNameDisplayer nnd = new NodeNameDisplayer(this);
        nnd.c = 0;
        ...
    }
    ...
}
```
8.18 Iterators

The `foreach` statement is used to iterate over the elements of an enumerable collection. In order to be enumerable, a collection shall have a parameterless `GetEnumerator` method that returns an enumerator. Generally, enumerators are difficult to implement, but the task is significantly simplified with iterators.

An iterator is a statement block that yields an ordered sequence of values. An iterator is distinguished from a normal statement block by the presence of one or more `yield` statements:

- The `yield return` statement produces the next value of the iteration.
- The `yield break` statement indicates that the iteration is complete.

An iterator can be used as the body of a function member as long as the return type of the function member is one of the enumerator interfaces or one of the enumerable interfaces:

- The enumerator interfaces are `System.Collections.IEnumerator` and types constructed from `System.Collections.Generic.IEnumerator<T>`.
- The enumerable interfaces are `System.Collections.IEnumerable` and types constructed from `System.Collections.Generic.IEnumerable<T>`.

It is important to understand that an iterator is not a kind of member, but is a means of implementing a function member. A member implemented via an iterator can be overridden or overloaded by other members, which may or may not be implemented with iterators.

The following `Stack<T>` class implements its `GetEnumerator` method using an iterator, which enumerates the elements of the stack in top-to-bottom order.

```csharp
using System.Collections.Generic;

public class Stack<T>: IEnumerable<T>
{
    T[] items;
    int count;
    public void Push(T data) {...}
    public T Pop() {...}
    public IEnumerator<T> GetEnumerator() {
        for (int i = count - 1; i >= 0; --i) {
            yield return items[i];
        }
    }
}
```
The presence of the GetEnumerator method makes Stack<T> an enumerable type, allowing instances of Stack<T> to be used in a foreach statement. The following example pushes the values 0 through 9 onto an integer stack and then uses a foreach loop to display the values in top-to-bottom order.

```csharp
using System;

class Test
{
    static void Main()
    {
        Stack<int> s = new Stack<int>();
        for (int i = 0; i < 10; i++) s.Push(i);
        foreach (int i in s) Console.Write("{0} ", i);
        Console.WriteLine();
    }
}
```

The output of the example is:

```
9 8 7 6 5 4 3 2 1 0
```

The foreach statement implicitly calls a collection’s parameterless GetEnumerator method to obtain an enumerator. There can only be one such parameterless GetEnumerator method defined by a collection, yet it is often appropriate to have multiple ways of enumerating, and ways of controlling the enumeration through parameters. In such cases, a collection can use iterators to implement properties or methods that return one of the enumerable interfaces. For example, Stack<T> might introduce two new properties, TopToBottom and BottomToTop, of type IEnumerable<T>:

```csharp
using System.Collections.Generic;
public class Stack<T>: IEnumerable<T>
{
    T[] items;
    int count;

    public void Push(T data) {...}
    public T Pop() {...}

    public IEnumerator<T> GetEnumerator() {
        for (int i = count – 1; i >= 0; --i) {
            yield return items[i];
        }
    }

    public IEnumerable<T> TopToBottom {
        get {
            return this;
        }
    }

    public IEnumerable<T> BottomToTop {
        get {
            for (int i = 0; i < count; i++) {
                yield return items[i];
            }
        }
    }
}
```

The get accessor for the TopToBottom property just returns this since the stack itself is an enumerable. The BottomToTop property returns an enumerable implemented with an iterator. The following example shows how the properties can be used to enumerate stack elements in either order:

```csharp
using System;

class Test
{
    static void Main()
    {
        Stack<int> s = new Stack<int>();
        for (int i = 0; i < 10; i++) s.Push(i);
    }
}
```
foreach (int i in s.TopToBottom) Console.Write("{0} ", i);
Console.WriteLine();
foreach (int i in s.BottomToTop) Console.Write("{0} ", i);
Console.WriteLine();
}

Of course, these properties can be used outside of a foreach statement as well. The following example
passes the results of invoking the properties to a separate Print method. The example also shows an iterator
used as the body of a FromToBy method that takes parameters:

using System;
using System.Collections.Generic;
class Test
{
    static void Print(IEnumerable<int> collection) {
        foreach (int i in collection) Console.Write("{0} ", i);
        Console.WriteLine();
    }
    static IEnumerable<int> FromToBy(int from, int to, int by) {
        for (int i = from; i <= to; i += by) {
            yield return i;
        }
    }
    static void Main() {
        Stack<int> s = new Stack<int>();
        for (int i = 0; i < 10; i++) s.Push(i);
        Print(s.TopToBottom);
        Print(s.BottomToTop);
        Print(FromToBy(10, 20, 2));
    }
}

The output of the example is:
9 8 7 6 5 4 3 2 1 0
0 1 2 3 4 5 6 7 8 9
10 12 14 16 18 20

The generic and non-generic enumerable interfaces contain a single member, a GetEnumerator method
that takes no arguments and returns an enumerator interface. An enumerable acts as an enumerator factory.
Properly implemented enumerables generate independent enumerators each time their GetEnumerator
method is called. Assuming the internal state of the enumerable has not changed between two calls to
GetEnumerator, the two enumerators returned should produce the same set of values in the same order.
This should hold even if the lifetimes of the enumerators overlap as in the following code sample:

using System;
using System.Collections.Generic;
class Test
{
    static IEnumerable<int> FromTo(int from, int to) {
        while (from <= to) yield return from++;
    }
    static void Main() {
        IEnumerable<int> e = FromTo(1, 10);
        foreach (int x in e) {
            foreach (int y in e) {
                Console.Write("{0,3} ", x * y);
            }
            Console.WriteLine();
        }
    }
}
The code above prints a simple multiplication table of the integers 1 through 10. Note that the `FromTo` method is invoked only once to generate the enumerable `e`. However, `e.GetEnumerator()` is invoked multiple times (by the `foreach` statements) to generate multiple equivalent enumerators. These enumerators all encapsulate the iterator code specified in the declaration of `FromTo`. Note that the iterator code modifies the `from` parameter. Nevertheless, the enumerators act independently because each enumerator is given its own copy of the `from` and `to` parameters. The sharing of transient state between enumerators is one of several common subtle flaws that should be avoided when implementing enumerables and enumerators. Iterators are designed to help avoid these problems and to implement robust enumerables and enumerators in a simple intuitive way.

### 8.19 Nullable types

Support for nullability across all types, including value types, is essential when interacting with databases; yet, historically, general-purpose programming languages have provided little or no support in this area. Many approaches exist for handling nulls and value types without direct language support, but all have shortcomings. For example, one approach is to use a “special” value (such as `-1` for integers) to indicate null, but this only works when an unused value can be identified. Another approach is to maintain Boolean null indicators in separate fields or variables, but this doesn’t work well for parameters and return values. A third approach is to use a set of user-defined nullable types, but this only works for a closed set of types. C#’s **nullable types** solve this long-standing problem by providing complete and integrated support for nullable forms of all value types.

Nullable types are constructed using the `?` type modifier. For example, `int?` is the nullable form of the predefined type `int`. A nullable type’s underlying type must be a non-nullable value type.

A nullable type is a structure that combines a value of the underlying type with a Boolean null indicator. An instance of a nullable type has two public read-only properties: `HasValue`, of type `bool`, and `Value`, of the nullable type’s underlying type. `HasValue` is true for a non-null instance and false for a null instance. When `HasValue` is true, the `Value` property returns the contained value. When `HasValue` is false, an attempt to access the `Value` property throws an exception.

An implicit conversion exists from any non-nullable value type to a nullable form of that type. Furthermore, an implicit conversion exists from the `null` type (§11.2.7) to any nullable type. In the example

```csharp
int i = 123;
int? x = i;    // int --> int?
double? y = x;   // int? --> double?
int? z = (int?)y;  // double? --> int?
int j = (int?)z;  // int? --> int
```

the `int` value `123` and the `null` literal are implicitly converted to the nullable type `int?`. The example outputs `123` for `x`, but the second `Console.WriteLine` isn’t executed because `y.HasValue` is false.

**Nullable conversions** and **lifted conversions** permit predefined and user-defined conversions that operate on non-nullable value types also to be used with nullable forms of those types. Likewise, **lifted operators** permit predefined and user-defined operators that work for non-nullable value types also to work for nullable forms of those types.

For every predefined conversion from a non-nullable value type `S` to a non-nullable value type `T`, a predefined nullable conversion automatically exists from `S?` to `T?`. This nullable conversion is a **null propagating** form of the underlying conversion: It converts a null source value directly to a null target value, but otherwise performs the underlying non-nullable conversion. Nullable conversions are furthermore provided from `S` to `T?` and from `S?` to `T`, the latter as an explicit conversion that throws an exception if the source value is null.

Some examples of nullable conversions are shown in the following.

```csharp
int i = 123;
int? x = i;    // int --> int?
double? y = x;   // int? --> double?
int? z = (int?)y;  // double? --> int?
int j = (int?)z;  // int? --> int
```
A user-defined conversion operator has a lifted form when the source and target types are both non-nullable value types. A ? modifier is added to the source and target types to create the lifted form. Similar to predefined nullable conversions, lifted conversion operators propagate nulls.

A non-comparison operator has a lifted form when the operand types and result type are all non-nullable value types. For non-comparison operators, a ? modifier is added to each operand type and the result type to create the lifted form. For example, the lifted form of the predefined + operator that takes two int operands and returns an int, is an operator that takes two int? operands and returns an int?. Similar to lifted conversions, lifted non-comparison operators are null-propagating: If either operand of a lifted operator is null, the result is null.

The following example uses a lifted + operator to add two int? values:

```csharp
int? x = GetNullableInt();
int? y = GetNullableInt();
int? z = x + y;
```

the assignment to z effectively corresponds to:

```csharp
int? z = x.HasValue && y.HasValue ? x.Value + y.Value : (int?)null;
```

Because an implicit conversion exists from a non-nullable value type to its nullable form, a lifted operator is applicable when just one operand is of a nullable type. The following example uses the same lifted + operator as the example above:

```csharp
int? x = GetNullableInt();
int? y = x + 1;
```

If x is null, y is assigned null. Otherwise, y is assigned the value of x plus one.

The null-propagating semantics of C#’s nullable conversions, lifted conversions, and lifted non-comparison operators are very similar to the corresponding conversions and operators in SQL. However, C#’s lifted comparison operators produce regular Boolean results rather than introducing SQL’s three-valued Boolean logic.

A comparison operator (==, !=, <, >, <=, >=) has a lifted form when the operand types are both non-nullable value types and the result type is bool. The lifted form of a comparison operator is formed by adding a ? modifier to each operand type (but not to the result type). Lifted forms of the == and != operators consider two null values equal, and a null value unequal to a non-null value. Lifted forms of the <, >, <=, and >= operators return false if one or both operands are null.

When one of the operands of the == or != operator has the null type (§11.2.7), the other operand may be of any nullable type regardless of whether the underlying value type actually declares that operator. In cases where no operator == or != implementation is available, a check of the operand’s HasValue property is substituted. The effect of this rule is that statements such as

```csharp
if (x == null) Console.WriteLine("x is null");
if (x != null) Console.WriteLine("x is non-null");
```

are permitted for an x of any nullable type or reference type, thus providing a common way of performing null checks for all types that can be null.

A new null coalescing operator, ??, is provided. The result of a ?? b is a if a is non-null; otherwise, the result is b. Intuitively, b supplies the value to use when a is null.

When a is of a nullable type and b is of a non-nullable type, a ?? b returns a non-nullable value, provided the appropriate implicit conversions exist between the operand types. In the example

```csharp
int? x = GetNullableInt();
int? y = GetNullableInt();
int? z = x ?? y;
int i = z ?? -1;
```

the type of x ?? y is int?, but the type of z ?? -1 is int. The latter operation is particularly convenient because it removes the ? from the type and at the same time supplies the default value to use in the null case.
The null coalescing operator also works for reference types. The example

```csharp
    string s = GetStringValue();
    Console.WriteLine(s ?? "Unspecified");
```

outputs the value of `s`, or outputs `Unspecified` if `s` is null.

9. Lexical structure

9.1 Programs

A C# program consists of one or more source files, known formally as compilation units (§16.1). A source file is an ordered sequence of Unicode characters. Source files typically have a one-to-one correspondence with files in a file system, but this correspondence is not required.

Conceptually speaking, a program is compiled using three steps:

1. Transformation, which converts a file from a particular character repertoire and encoding scheme into a sequence of Unicode characters.
2. Lexical analysis, which translates a stream of Unicode input characters into a stream of tokens.
3. Syntactic analysis, which translates the stream of tokens into executable code.

Conforming implementations shall accept Unicode source files encoded with the UTF-8 encoding form (as defined by the Unicode standard), and transform them into a sequence of Unicode characters. Implementations can choose to accept and transform additional character encoding schemes (such as UTF-16, UTF-32, or non-Unicode character mappings).

[Note: It is beyond the scope of this standard to define how a file using a character representation other than Unicode might be transformed into a sequence of Unicode characters. During such transformation, however, it is recommended that the usual line-separating character (or sequence) in the other character set be translated to the two-character sequence consisting of the Unicode carriage-return character followed by Unicode line-feed character. For the most part this transformation will have no visible effects; however, it will affect the interpretation of verbatim string literal tokens (§9.4.4.5). The purpose of this recommendation is to allow a verbatim string literal to produce the same character sequence when its source file is moved between systems that support differing non-Unicode character sets, in particular, those using differing character sequences for line-separation. end note]

9.2 Grammars

This specification presents the syntax of the C# programming language using two grammars. The lexical grammar (§9.2.1) defines how Unicode characters are combined to form line terminators, white space, comments, tokens, and pre-processing directives. The syntactic grammar (§9.2.2) defines how the tokens resulting from the lexical grammar are combined to form C# programs.

9.2.1 Lexical grammar

The lexical grammar of C# is presented in §9.3, §9.4, and §9.5. The terminal symbols of the lexical grammar are the characters of the Unicode character set, and the lexical grammar specifies how characters are combined to form tokens (§9.4), white space (§9.3.3), comments (§9.3.2), and pre-processing directives (§9.5).

Every source file in a C# program shall conform to the input production of the lexical grammar (§9.3).

9.2.2 Syntactic grammar

The syntactic grammar of C# is presented in the clauses, subclauses, and appendices that follow this subclause. The terminal symbols of the syntactic grammar are the tokens defined by the lexical grammar, and the syntactic grammar specifies how tokens are combined to form C# programs.
Every source file in a C# program shall conform to the compilation-unit production (§16.1) of the syntactic grammar.

9.2.3 Grammar ambiguities

The productions for simple-name (§14.5.2) and member-access (§14.5.4) can give rise to ambiguities in the grammar for expressions. [Example: The statement:

```csharp
F(G<A, B>(7));
```

could be interpreted as a call to F with two arguments, G < A and B > (7). Alternatively, it could be interpreted as a call to F with one argument, which is a call to a generic method G with two type arguments and one regular argument. end example]

If a sequence of tokens can be parsed (in context) as a simple-name (§14.5.2), member-access (§14.5.4), or pointer-member-access (§27.5.2) ending with a type-argument-list (§25.5.1), the token immediately following the closing > token is examined. If it is one of

```csharp
( ) : ; , ? == !=
```

then the type-argument-list is retained as part of the simple-name, member-access or pointer-member-access and any other possible parse of the sequence of tokens is discarded. Otherwise, the type-argument-list is not considered part of the simple-name, member-access or pointer-member-access, even if there is no other possible parse of the sequence of tokens. [Note: These rules are not applied when parsing a type-argument-list in a namespace-or-type-name (§10.8). end note] [Example: The statement:

```csharp
F(G<A, B>(7));
```

will, according to this rule, be interpreted as a call to F with one argument, which is a call to a generic method G with two type arguments and one regular argument. The statements

```csharp
F(G<A, B>7);
F(G<A, B>B>7);
```

will each be interpreted as a call to F with two arguments. The statement

```csharp
x = F<A> + y;
```

will be interpreted as a less-than operator, greater-than operator and unary-plus operator, as if the statement had been written `x = (F < A) > (+y)`, instead of as a simple-name with a type-argument-list followed by a binary-plus operator. In the statement

```csharp
x = y |s <T> + z;
```

the tokens `<T>` are interpreted as a namespace-or-type-name with a type-argument-list. end example]

9.3 Lexical analysis

The input production defines the lexical structure of a C# source file. Each source file in a C# program shall conform to this lexical grammar production.

```csharp
input::
  input-section_opt
input-section::
  input-section-part
  input-section input-section-part
input-section-part::
  input-elements_opt new-line
  pp-directive
input-elements::
  input-element
  input-elements input-element
```
Five basic elements make up the lexical structure of a C# source file: Line terminators (§9.3.1), white space (§9.3.3), comments (§9.3.2), tokens (§9.4), and pre-processing directives (§9.5). Of these basic elements, only tokens are significant in the syntactic grammar of a C# program (§9.2.2), except in the case of a > token being combined with another token to form a single operator (§9.4.5).

The lexical processing of a C# source file consists of reducing the file into a sequence of tokens which becomes the input to the syntactic analysis. Line terminators, white space, and comments can serve to separate tokens, and pre-processing directives can cause sections of the source file to be skipped, but otherwise these lexical elements have no impact on the syntactic structure of a C# program.

When several lexical grammar productions match a sequence of characters in a source file, the lexical processing always forms the longest possible lexical element. [Example: The character sequence // is processed as the beginning of a single-line comment because that lexical element is longer than a single / token. end example]

9.3.1 Line terminators
Line terminators divide the characters of a C# source file into lines.

\[
\text{new-line::} \\
\text{Carriage return character (U+000D)} \\
\text{Line feed character (U+000A)} \\
\text{Carriage return character (U+000D) followed by line feed character (U+000A)} \\
\text{Next line character (U+2085)} \\
\text{Line separator character (U+2028)} \\
\text{Paragraph separator character (U+2029)}
\]

For compatibility with source code editing tools that add end-of-file markers, and to enable a source file to be viewed as a sequence of properly terminated lines, the following transformations are applied, in order, to every source file in a C# program:

- If the last character of the source file is a Control-Z character (U+001A), this character is deleted.
- A carriage-return character (U+000D) is added to the end of the source file if that source file is non-empty and if the last character of the source file is not a carriage return (U+000D), a line feed (U+000A), a next line character (U+2085), a line separator (U+2028), or a paragraph separator (U+2029). [Note: The additional carriage-return allows a program to end in a pp-directive (§9.5) that does not have a terminating new-line. end note]

9.3.2 Comments
Two forms of comments are supported: delimited comments and single-line comments.

A delimited comment begins with the characters /* and ends with the characters */. Delimited comments can occupy a portion of a line, a single line, or multiple lines. [Example: The example

\[
/\ast\text{ Hello, world program} \\
\text{ This program writes “hello, world” to the console}\n\]

\[
/\ast\text{ Hello}\n\]

\[
class \text{ Hello}\n\]

\[
\{\text{ static void Main() { System.Console.WriteLine("hello, world"); } }\n\]

includes a delimited comment. end example]
A single-line comment begins with the characters // and extends to the end of the line. [Example: The example

    // Hello, world program
    // This program writes “hello, world” to the console
    //
    class Hello // any name will do for this class
    {
        static void Main() { // this method must be named "Main"
            System.Console.WriteLine("hello, world");
        }
    }

shows several single-line comments. end example]

    comment::
        single-line-comment
        delimited-comment

    single-line-comment::
        // input-charactersopt

    input-characters::
        input-character
        input-characters input-character

    input-character::
        Any Unicode character except a new-line-character

    new-line-character::
        Carriage return character (U+000D)
        Line feed character (U+000A)
        Next line character (U+0085)
        Line separator character (U+2028)
        Paragraph separator character (U+2029)

    delimited-comment::
        /* delimited-comment-textopt asterisks */

    delimited-comment-text::
        delimited-comment-section
        delimited-comment-text delimited-comment-section

    delimited-comment-section::
        not-asterisk
        asterisks not-slash

    asterisks::
        *
        asterisks *

    not-asterisk::
        Any Unicode character except *

    not-slash::
        Any Unicode character except /

Comments do not nest. The character sequences /* and */ have no special meaning within a single-line comment, and the character sequences // and /* have no special meaning within a delimited comment. Comments are not processed within character and string literals.
9.3.3 White space
White space is defined as any character with Unicode class Zs (which includes the space character) as well as the horizontal tab character, the vertical tab character, and the form feed character.

\[
\text{whitespace} ::
whitespace-characters
\]

\[
\text{whitespace-characters} ::
whitespace-character
whitespace-characters whitespace-character
\]

\[
\text{whitespace-character} ::
\text{Any character with Unicode class Zs}
\text{Horizontal tab character (U+0009)}
\text{Vertical tab character (U+000B)}
\text{Form feed character (U+000C)}
\]

9.4 Tokens
There are several kinds of tokens: identifiers, keywords, literals, operators, and punctuators. White space and comments are not tokens, though they act as separators for tokens.

\[
\text{token} ::
\text{identifier}
\text{keyword}
\text{integer-literal}
\text{real-literal}
\text{character-literal}
\text{string-literal}
\text{operator-or-punctuator}
\]

9.4.1 Unicode escape sequences
A Unicode escape sequence represents a Unicode character. Unicode escape sequences are processed in identifiers (§9.4.2), regular string literals (§9.4.4.5), and character literals (§9.4.4.4). A Unicode character escape is not processed in any other location (for example, to form an operator, punctuator, or keyword).

\[
\text{unicode-escape-sequence} ::
\text{\u hex-digit hex-digit hex-digit hex-digit}
\text{\U hex-digit hex-digit hex-digit hex-digit hex-digit hex-digit hex-digit hex-digit}
\]

A Unicode escape sequence represents the single Unicode character formed by the hexadecimal number following the “\u” or “\U” characters. Since C# uses a 16-bit encoding of Unicode characters in characters and string values, a Unicode code point in the range U+10000 to U+10FFFF is represented using two Unicode surrogate code units. Unicode code points above 0x10FFFF are invalid and are not supported.

Multiple translations are not performed. For instance, the string literal “\u005Cu005C” is equivalent to “\u005C” rather than “\”. [Note: The Unicode value \u005C is the character “\”. end note]

[Example: The example
\[
\begin{align*}
\text{class Class1} \\
&\{ \\
&\quad \text{static void Test(bool } \text{\u0066) } \\
&\quad \quad \text{char } c = '\text{\u0066}'; \\
&\quad \quad \text{if } (\text{\u0066}) \\
&\quad \quad \quad \text{System.Console.WriteLine(c.ToString());} \\
&\quad \} \\
\end{align*}
\]

shows several uses of \u0066, which is the escape sequence for the letter “f”. The program is equivalent to
class Class1
{
    static void Test(bool f) {
        char c = 'f';
        if (f)
            System.Console.WriteLine(c.ToString());
    }
}

9.4.2 Identifiers

The rules for identifiers given in this subclause correspond exactly to those recommended by the Unicode Standard Annex 15 except that underscore is allowed as an initial character (as is traditional in the C programming language), Unicode escape sequences are permitted in identifiers, and the “@” character is allowed as a prefix to enable keywords to be used as identifiers.

identifier::
    available-identifier
    @ identifier-or-keyword

available-identifier::
    An identifier-or-keyword that is not a keyword

identifier-or-keyword::
    identifier-start-character identifier-part-characters

identifier-start-character::
    letter-character
    _ (the underscore character U+005F)

identifier-part-characters::
    identifier-part-character
    identifier-part-characters opt

identifier-part-character::
    letter-character
    decimal-digit-character
    connecting-character
    combining-character
    formatting-character

letter-character::
    A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Ni
    A unicode-escape-sequence representing a character of classes Lu, Ll, Lt, Lm, Lo, or Ni

combining-character::
    A Unicode character of classes Mn or Mc
    A unicode-escape-sequence representing a character of classes Mn or Mc

decimal-digit-character::
    A Unicode character of the class Nd
    A unicode-escape-sequence representing a character of the class Nd

connecting-character::
    A Unicode character of the class Pc
    A unicode-escape-sequence representing a character of the class Pc

formatting-character::
    A Unicode character of the class Cf
    A unicode-escape-sequence representing a character of the class Cf
9 Lexical structure

[Note: For information on the Unicode character classes mentioned above, see The Unicode Standard, Version 3.0, §4.5. end note]

[Example: Examples of valid identifiers include “identifier1”, “_identifier2”, and “@if”. end example]

An identifier in a conforming program shall be in the canonical format defined by Unicode Normalization Form C, as defined by Unicode Standard Annex 15. The behavior when encountering an identifier not in Normalization Form C is implementation-defined; however, a diagnostic is not required.

The prefix “@” enables the use of keywords as identifiers, which is useful when interfacing with other programming languages. The character @ is not actually part of the identifier, so the identifier might be seen in other languages as a normal identifier, without the prefix. An identifier with an @ prefix is called a verbatim identifier. [Note: Use of the @ prefix for identifiers that are not keywords is permitted, but strongly discouraged as a matter of style. end note]

[Example: The example:

class @class
{
    public static void @static(bool @bool) {
        if (@bool)
            System.Console.WriteLine("true");
        else
            System.Console.WriteLine("false");
    }
}
class Class1
{
    static void M() {
        cl\u0061ss.st\u0061tic(true);
    }
}

defines a class named “class” with a static method named “static” that takes a parameter named “bool”. Note that since Unicode escapes are not permitted in keywords, the token “cl\u0061ss” is an identifier, and is the same identifier as “@class”. end example]

Two identifiers are considered the same if they are identical after the following transformations are applied, in order:

- The prefix “@”, if used, is removed.
- Each unicode-escape-sequence is transformed into its corresponding Unicode character.
- Any formatting-characters are removed.

Identifiers containing two consecutive underscore characters (U+005F) are reserved for use by the implementation; however, no diagnostic is required if such an identifier is defined. [Note: For example, an implementation might provide extended keywords that begin with two underscores. end note]

9.4.3 Keywords

A keyword is an identifier-like sequence of characters that is reserved, and cannot be used as an identifier except when prefaced by the @ character.
keyword:: one of
abstract as base bool break
byte case catch char checked
class const continue decimal default
delegate do double else enum
event explicit extern false finally
fixed float for foreach goto
if implicit in int interface
internal is lock long namespace
new null object operator out
override params private protected public
readonly ref return sbyte sealed
short sizeof stackalloc static string
struct switch this throw true
try typeof uint ulong unchecked
unsafe ushort using virtual void
volatile while

The following identifiers have special meaning in the syntactic grammar, but they are not keywords: add (§17.7), alias (§16.3), get (§17.6.2), global (§16.7), partial (§17.1.4), remove (§17.7), set (§17.6.2), value (§17.6.2, §17.7.2), where (§25.7), and yield (§15.14). For convenience and clarity, these identifiers appear as terminals in the syntactic grammar; however, they are identifiers. [Note: As a result, unlike keywords, these identifiers can be written with a @ prefix and can contain unicode-escape-sequences. end note]

9.4.4 Literals

A literal (§14.5.1) is a source code representation of a value.

9.4.4.1 Boolean literals

There are two Boolean literal values: true and false.

    boolean-literal::
        true
        false

The type of a boolean-literal is bool.

9.4.4.2 Integer literals

Integer literals are used to write values of types int, uint, long, and ulong. Integer literals have two possible forms: decimal and hexadecimal.

    integer-literal::
        decimal-integer-literal
        hexadecimal-integer-literal

    decimal-integer-literal::
        decimal-digits integer-type-suffixopt

    decimal-digits::
        decimal-digit
        decimal-digits decimal-digit

    decimal-digit::
        one of
        0 1 2 3 4 5 6 7 8 9

    integer-type-suffix::
        one of
        U u L l UL Ul uL Lu Lu ul uU uL
hexadecimal-integer.literal::
   0x hex-digits integer-type-suffixopt
   0X hex-digits integer-type-suffixopt

hex-digits::
   hex-digit
   hex-digits hex-digit

hex-digit:: one of
   0 1 2 3 4 5 6 7 8 9 A B C D E F a b c d e f

The type of an integer literal is determined as follows:

- If the literal has no suffix, it has the first of these types in which its value can be represented: int, uint, long, ulong.
- If the literal is suffixed by U or u, it has the first of these types in which its value can be represented: uint, ulong.
- If the literal is suffixed by L or l, it has the first of these types in which its value can be represented: long, ulong.
- If the literal is suffixed by UL, Ul, uL, Lu, Lu, ul, 1u, or 1u, it is of type ulong.

If the value represented by an integer literal is outside the range of the ulong type, a compile-time error occurs.

[Note: As a matter of style, it is suggested that “L” be used instead of “l” when writing literals of type long, since it is easy to confuse the letter “l” with the digit “1”. end note]

To permit the smallest possible int and long values to be written as decimal integer literals, the following two rules exist:

- When a decimal-integer.literal with the value 2147483648 (2^{31}) and no integer-type-suffix appears as the token immediately following a unary minus operator token (§14.6.2), the result (of both tokens) is a constant of type int with the value −2147483648 (−2^{31}). In all other situations, such a decimal-integer.literal is of type uint.
- When a decimal-integer.literal with the value 9223372036854775808 (2^{63}) and no integer-type-suffix or the integer-type-suffix L or l appears as the token immediately following a unary minus operator token (§14.6.2), the result (of both tokens) is a constant of type long with the value −9223372036854775808 (−2^{63}). In all other situations, such a decimal-integer.literal is of type ulong.

9.4.4.3 Real literals

Real literals are used to write values of types float, double, and decimal.

real.literal::
   decimal-digits . decimal-digits exponent-part_opt real-type-suffix_opt
   . decimal-digits exponent-part_opt real-type-suffix_opt
   decimal-digits exponent-part real-type-suffix_opt
   decimal-digits real-type-suffix

exponent-part::
   e sign_opt decimal-digits
   E sign_opt decimal-digits

sign:: one of
   + -

real-type-suffix:: one of
   F f D d M m
If no real-type-suffix is specified, the type of the real literal is `double`. Otherwise, the real-type-suffix determines the type of the real literal, as follows:

- A real literal suffixed by `F` or `f` is of type `float`. [Example: The literals `1f`, `1.5f`, `1e10f`, and `123.456F` are all of type `float`. end example]
- A real literal suffixed by `D` or `d` is of type `double`. [Example: The literals `1d`, `1.5d`, `1e10d`, and `123.456D` are all of type `double`. end example]
- A real literal suffixed by `M` or `m` is of type `decimal`. [Example: The literals `1m`, `1.5m`, `1e10m`, and `123.456M` are all of type `decimal`. end example] This literal is converted to a decimal value by taking the exact value, and, if necessary, rounding to the nearest representable value using banker's rounding (§11.1.7). Any scale apparent in the literal is preserved unless the value is rounded. [Note: Hence, the literal `2.900m` will be parsed to form the `decimal` with sign 0, coefficient 2900, and scale 3. end note]

If the specified literal is too large to be represented in the indicated type, a compile-time error occurs. [Note: In particular, a real-literal will never produce a floating-point infinity. A non-zero real-literal may, however, be rounded to zero. end note]

The value of a real literal having type `float` or `double` is determined by using the IEC 60559 “round to nearest” mode.

9.4.4.4 Character literals

A character literal represents a single character, and usually consists of a character in quotes, as in `'a'`.

```
character-literal::
  ' character '

canonical-escape-sequence::
  \character

character::
  single-character
  simple-escape-sequence
  hexadecimal-escape-sequence
  unicode-escape-sequence

canonical-escape-sequence::
  one of
  ' " \  \a \b \f \n \r \t \v

digit::
  digit opt

digit-opt::
  digit

hexadecimal-escape-sequence::
  \x hex-digit hex-digit_opt

unicode-escape-sequence::
  \u hex-digit hex-digit_opt hex-digit_opt hex-digit_opt
```

[Note: A character that follows a backslash character (`\`) in a character shall be one of the following characters: `'`, `"`, `\`, `0`, `a`, `b`, `f`, `n`, `r`, `t`, `u`, `U`, `x`, `v`. Otherwise, a compile-time error occurs. end note]

A hexadecimal escape sequence represents a single Unicode character, with the value formed by the hexadecimal number following “\x”.

If the value represented by a character literal is greater than `U+FFFF`, a compile-time error occurs.

A Unicode character escape sequence (§9.4.1) in a character literal shall be in the range `U+0000` to `U+FFFF`.

A simple escape sequence represents a Unicode character encoding, as described in the table below.
The type of a character-literal is char.

9.4.4.5 String literals

C# supports two forms of string literals: regular string literals and verbatim string literals. A regular string literal consists of zero or more characters enclosed in double quotes, as in "hello, world", and can include both simple escape sequences (such as \t for the tab character), and hexadecimal and Unicode escape sequences.

A verbatim string literal consists of an @ character followed by a double-quote character, zero or more characters, and a closing double-quote character. [Example: A simple example is @"hello, world". end example] In a verbatim string literal, the characters between the delimiters are interpreted verbatim, with the only exception being a quote-escape-sequence, which represents one double-quote character. In particular, simple escape sequences, and hexadecimal and Unicode escape sequences are not processed in verbatim string literals. A verbatim string literal can span multiple lines.

```
string-literal::
  regular-string-literal
  verbatim-string-literal

regular-string-literal::
  "  regular-string-literal-charactersopt  "

regular-string-literal-characters::
  regular-string-literal-character
  regular-string-literal-characters   regular-string-literal-character

regular-string-literal-character::
  single-regular-string-literal-character
  simple-escape-sequence
  hexadecimal-escape-sequence
  unicode-escape-sequence

single-regular-string-literal-character::
  Any character except " (U+0022), \ (U+005C), and new-line-character

verbatim-string-literal::
  @"  verbatim-string-literal-charactersopt  "
```
verbatim-string-literal-characters::
  verbatim-string-literal-character
  verbatim-string-literal-characters   verbatim-string-literal-character

verbatim-string-literal-character::
  single-verbatim-string-literal-character
  quote-escape-sequence

single-verbatim-string-literal-character::
  Any character except "

quote-escape-sequence::
  \\

[Note: A character that follows a backslash character (\) in a regular-string-literal-character shall be one of the following characters: ', '', \, 0, a, b, f, n, r, t, u, v, x, v. Otherwise, a compile-time error occurs. end note]

[Example: The example
  string a = "Happy birthday, Joel";   // Happy birthday, Joel
  string b = @"Happy birthday, Joel"; // Happy birthday, Joel
  string c = "hello \t world";       // hello \t world
  string d = @"hello \t world";     // hello \t world
  string e = "Joe said \"Hello\" to me"; // Joe said "Hello" to me
  string f = @"Joe said ""Hello"" to me"; // Joe said "Hello" to me
  string g = "\\server\share\file.txt"; // \server\share\file.txt
  string h = @\\server\share\file.txt"; // \server\share\file.txt
  string i = "one\r\ntwo\r\nthree";
  string j = @"one\n\ntwo\n\nthree";
shows a variety of string literals. The last string literal, j, is a verbatim string literal that spans multiple lines. The characters between the quotation marks, including white space such as new line characters, are preserved verbatim, and each pair of double-quote characters is replaced by one such character. end example]

[Note: Since a hexadecimal escape sequence can have a variable number of hex digits, the string literal "\x123" contains a single character with hex value 123. To create a string containing the character with hex value 12 followed by the character 3, one could write "\x00123" or "\x12" + "3" instead. end note]

The type of a string-literal is string.

Each string literal does not necessarily result in a new string instance. When two or more string literals that are equivalent according to the string equality operator (§14.9.7), appear in the same assembly, these string literals refer to the same string instance. [Example: For instance, the output produced by
  class Test
  {
    static void Main() {
      object a = "hello";
      object b = "hello";
      System.Console.WriteLine(a == b);
    }
  }
  
is True because the two literals refer to the same string instance. end example]

9.4.4.6 The null literal

null-literal:::
  null

The type of a null-literal is the null type (§11.2.7).
9 Lexical structure

9.4.5 Operators and punctuators

There are several kinds of operators and punctuators. Operators are used in expressions to describe operations involving one or more operands. [Example: The expression \( a + b \) uses the \( + \) operator to add the two operands \( a \) and \( b \). end example] Punctuators are for grouping and separating.

\[
\text{operator-or-punctuator:: one of }
\{  \}  \[  \]  (  )  .  ,  :  ;  \\
+  -  *  /  %  &  |  ^  !  ~  \\
=  <  >  ?  ??  ::  ++  -=  &&  ||  \\
->  ==  !=  <=  >=  +=  -=  *=  /=  %=  \\
&=  |=  ^=  <<=  <<==
\]

\[
\text{right-shift::}
\]
\[
>  >
\]

\[
\text{right-shift-assignment::}
\]
\[
>  >=
\]

right-shift is made up of the two tokens \( > \) and \( > \). Similarly, right-shift-assignment is made up of the two tokens \( > \) and \( >= \). Unlike other productions in the syntactic grammar, no characters of any kind (not even whitespace) are allowed between the two tokens in each of these productions. [Note: Prior to the addition of generics to C#, \( >> \) and \( >>= \) were both single tokens. However, the syntax for generics uses the \(< \) and \( > \) characters to delimit type parameters and type arguments. It is often desirable to use nested constructed types, such as \( \text{List<Dictionary<string, int>>} \). Rather than requiring the programmer to separate the \( > \) and \( > \) by a space, the definition of the two operator-or-punctuators was changed. end note]

9.5 Pre-processing directives

The pre-processing directives provide the ability to skip conditionally sections of source files, to report error and warning conditions, and to delineate distinct regions of source code. [Note: The term “pre-processing directives” is used only for consistency with the C and C++ programming languages. In C#, there is no separate pre-processing step; pre-processing directives are processed as part of the lexical analysis phase. end note]

\[
\text{pp-directive::}
\]
\[
\text{pp-declaration}  \\
\text{pp-conditional}  \\
\text{pp-line}  \\
\text{pp-diagnostic}  \\
\text{pp-region}  \\
\text{pp-pragmas}
\]

The following pre-processing directives are available:

- \#define and \#undef, which are used to define and undefine, respectively, conditional compilation symbols (§9.5.3).
- \#if, \#elif, \#else, and \#endif, which are used to skip conditionally sections of source code (§9.5.1).
- \#line, which is used to control line numbers emitted for errors and warnings (§9.5.7).
- \#error and \#warning, which are used to issue errors and warnings, respectively (§9.5.5).
- \#region and \#endregion, which are used to explicitly mark sections of source code (§9.5.6).
- \#pragma, which is used to provide contextual information to a compiler (§9.5.8).

A pre-processing directive always occupies a separate line of source code and always begins with a \# character and a pre-processing directive name. White space can occur before the \# character and between the \# character and the directive name.
A source line containing a `#define`, `#undef`, `#if`, `#elif`, `#else`, or `#endif` directive can end with a single-line comment. Delimited comments (the `/* */` style of comments) are not permitted on source lines containing pre-processing directives.

Pre-processing directives are not tokens and are not part of the syntactic grammar of C#. However, pre-processing directives can be used to include or exclude sequences of tokens and in that way can affect the meaning of a C# program. [Example: When compiled, the program

```csharp
#define A
#undef B
class C
{
  #if A
  void F() {}
  #else
  void G() {}
  #endif
  #if B
  void H() {}
  #else
  void I() {}
  #endif
}
```

results in the exact same sequence of tokens as the program

```csharp
class C
{
  void F() {}
  void I() {}
}
```

Thus, whereas lexically, the two programs are quite different, syntactically, they are identical. end example]

9.5.1 Conditional compilation symbols

The conditional compilation functionality provided by the `#if`, `#elif`, `#else`, and `#endif` directives is controlled through pre-processing expressions (§9.5.2) and conditional compilation symbols.

```
conditional-symbol::
  identifier
  Any keyword except true or false
```

A conditional compilation symbol has two possible states: defined or undefined. At the beginning of the lexical processing of a source file, a conditional compilation symbol is undefined unless it has been explicitly defined by an external mechanism (such as a command-line compiler option). When a `#define` directive is processed, the conditional compilation symbol named in that directive becomes defined in that source file. The symbol remains defined until a `#undef` directive for that same symbol is processed, or until the end of the source file is reached. An implication of this is that `#define` and `#undef` directives in one source file have no effect on other source files in the same program.

The name space for conditional compilation symbols is distinct and separate from all other named entities in a C# program. Conditional compilation symbols can only be referenced in `#define` and `#undef` directives and in pre-processing expressions.

9.5.2 Pre-processing expressions

Pre-processing expressions can occur in `#if` and `#elif` directives. The operators `,`, `,=, !, ==, !=, && and || are permitted in pre-processing expressions, and parentheses can be used for grouping.

```
pp-expression::
  whitespace_opt pp-or-expression whitespace_opt
```
When referenced in a pre-processing expression, a defined conditional compilation symbol has the Boolean value `true`, and an undefined conditional compilation symbol has the Boolean value `false`.

Evaluation of a pre-processing expression always yields a Boolean value. The rules of evaluation for a pre-processing expression are the same as those for a constant expression (§14.16), except that the only user-defined entities that can be referenced are conditional compilation symbols.

### 9.5.3 Declaration directives

The declaration directives are used to define or undefine conditional compilation symbols.

```
pp-declaration::
   whitespace   # whitespace   define whitespace   conditional-symbol   pp-new-line
   whitespace   # whitespace   undef whitespace   conditional-symbol   pp-new-line

pp-new-line::
   whitespace   single-line-comment   new-line
```

The processing of a `#define` directive causes the given conditional compilation symbol to become defined, starting with the source line that follows the directive. Likewise, the processing of a `#undef` directive causes the given conditional compilation symbol to become undefined, starting with the source line that follows the directive.

Any `#define` and `#undef` directives in a source file shall occur before the first token (§9.4) in the source file; otherwise a compile-time error occurs. In intuitive terms, `#define` and `#undef` directives shall precede any "real code" in the source file.

**Example:** The example:

```cpp
#define Enterprise
#if Professional || Enterprise
#define Advanced
#endif
namespace Megacorp.Data
{
#if Advanced
    class PivotTable {...}
#endif
}
```

is valid because the `#define` directives precede the first token (the `namespace` keyword) in the source file.
A `#define` can define a conditional compilation symbol that is already defined, without there being any intervening `#undef` for that symbol. [Example: The example below defines a conditional compilation symbol `A` and then defines it again.]

```csharp
#define A
#define A
```

For compilers that allow conditional compilation symbols to be defined as compilation options, an alternative way for such redefinition to occur is to define the symbol as a compiler option as well as in the source. [end example]

A `#undef` can “undefine” a conditional compilation symbol that is not defined. [Example: The example below defines a conditional compilation symbol `A` and then undefines it twice; although the second `#undef` has no effect, it is still valid.]

```csharp
#define A
#define A
#undef A
#undef A
```

9.5.4 Conditional compilation directives

The conditional compilation directives are used to conditionally include or exclude portions of a source file.

```csharp
pp-conditional::
  pp-if-section pp-elif-sections_opt pp-else-section_opt pp-endif

pp-if-section::
  whitespace_opt # whitespace_opt if whitespace pp-expression pp-new-line conditional-section_opt

pp-elif-sections::
  pp-elif-section
  pp-elif-sections pp-elif-section

pp-elif-section::
  whitespace_opt # whitespace_opt elif whitespace pp-expression pp-new-line conditional-section_opt

pp-else-section::
  whitespace_opt # whitespace_opt else pp-new-line conditional-section_opt

pp-endif::
  whitespace_opt # whitespace_opt endif pp-new-line conditional-section::
    input-section
    skipped-section
```
Lexical structure

[Note: As indicated by the syntax, conditional compilation directives shall be written as sets consisting of, in order, a \#if directive, zero or more \#elif directives, zero or one \#else directive, and a \#endif directive. Between the directives are conditional sections of source code. Each section is controlled by the immediately preceding directive. A conditional section can itself contain nested conditional compilation directives provided these directives form complete sets. end note]

A \textit{pp-conditional} selects at most one of the contained \textit{conditional-sections} for normal lexical processing:

- The \textit{pp-expressions} of the \#if and \#elif directives are evaluated in order until one yields \textit{true}. If an expression yields \textit{true}, the \textit{conditional-section} of the corresponding directive is selected.
- If all \textit{pp-expressions} yield \textit{false}, and if a \#else directive is present, the \textit{conditional-section} of the \#else directive is selected.
- Otherwise, no \textit{conditional-section} is selected.

The selected \textit{conditional-section}, if any, is processed as a normal \textit{input-section}: the source code contained in the section shall adhere to the lexical grammar; tokens are generated from the source code in the section; and pre-processing directives in the section have the prescribed effects.

The remaining \textit{conditional-sections}, if any, are processed as \textit{skipped-sections}: except for pre-processing directives, the source code in the section need not adhere to the lexical grammar; no tokens are generated from the source code in the section; and pre-processing directives in the section shall be lexically correct but are not otherwise processed. Within a \textit{conditional-section} that is being processed as a \textit{skipped-section}, any nested \textit{conditional-sections} (contained in nested \#if...\#endif and \#region...\#endregion constructs) are also processed as \textit{skipped-sections}.

[Example: The following example illustrates how conditional compilation directives can nest:

```c
#define Debug    // Debugging on
#undef Trace    // Tracing off

class PurchaseTransaction
{
    void Commit()
    {
        #if Debug
            CheckConsistency();
            #if Trace
                WriteToLog(this.ToString());
            #endif
            #endif
            CommitHelper();
        }
    }
    ...
}
```

Except for pre-processing directives, skipped source code is not subject to lexical analysis. For example, the following is valid despite the unterminated comment in the \#else section:

```c
#define Debug    // Debugging on
```
class PurchaseTransaction
{
    void Commit() {
        #if Debug
            CheckConsistency();
        #else
            /* Do something else */
        #endif
    }
}

Note, however, that pre-processing directives are required to be lexically correct even in skipped sections of source code.

Pre-processing directives are not processed when they appear inside multi-line input elements. For example, the program:

```c#
class Hello
{
    static void Main()
    {
        System.Console.WriteLine(@"hello,
            #if Debug
            world
            #else
            Nebraska
            #endif
        ");
    }
}
```
results in the output:

```
hello,
#if Debug
world
#else
Nebraska
#endif
```

In peculiar cases, the set of pre-processing directives that is processed might depend on the evaluation of the pp-expression. The example:

```
#if X
/*
#else  /* */ class Q { }
#endif
```
always produces the same token stream (class Q { }), regardless of whether or not X is defined. If X is defined, the only processed directives are #if and #endif, due to the multi-line comment. If X is undefined, then three directives (#if, #else, #endif) are part of the directive set. end example]

9.5.5 Diagnostic directives

The diagnostic directives are used to generate explicitly error and warning messages that are reported in the same way as other compile-time errors and warnings.

```
pp-diagnostic::
  whitespaceopt  #  whitespaceopt  error  pp-message
  whitespaceopt  #  whitespaceopt  warning  pp-message

pp-message::
  new-line
  whitespace  input-charactersopt  new-line
```

[Example: The example

```c#
#pragma warning Code review needed before check-in
```
#if Debug && Retail
#error A build can't be both debug and retail
#endif

class Test {...}

always produces a warning (“Code review needed before check-in”), and produces a compile-time error if the pre-processing identifiers Debug and Retail are both defined. Note that a pp-message can contain arbitrary text; specifically, it need not contain well-formed tokens, as shown by the single quote in the word can’t.  end example]

9.5.6 Region control
The region directives are used to mark explicitly regions of source code.

```
#region
   ...
#endregion
```

No semantic meaning is attached to a region; regions are intended for use by the programmer or by automated tools to mark a section of source code. The message specified in a #region or #endregion directive likewise has no semantic meaning; it merely serves to identify the region. Matching #region and #endregion directives can have different pp-messages.

The lexical processing of a region:

```
#region
   ...
#endregion
```

corresponds exactly to the lexical processing of a conditional compilation directive of the form:

```
#if true
   ...
#endif
```

9.5.7 Line directives
Line directives can be used to alter the line numbers and source file names that are reported by the compiler in output such as warnings and errors.

[Note: Line directives are most commonly used in meta-programming tools that generate C# source code from some other text input. end note]

```
pp-line::
   whitespaceopt # whitespaceopt line whitespace line-indicator pp-new-line

line-indicator::
   decimal-digits whitespace file-name
decimal-digits
identifier-or-keyword

file-name::
   " file-name-characters "

file-name-characters::
   file-name-character file-name-characters file-name-character
file-name-character::
   Any character except " (U+0022), and new-line-character
```
When no `#line` directives are present, the compiler reports true line numbers and source file names in its output. When processing a `#line` directive that includes a line-indicator that is not identifier-or-keyword, the compiler treats the line after the directive as having the given line number (and file name, if specified).

A `#line` directive in which the line-indicator is an identifier-or-keyword whose value equals `default` (using equality as specified in §9.4.2) reverses the effect of all preceding `#line` directives. The compiler reports true line information for subsequent lines, precisely as if no `#line` directives had been processed.

The purpose of a line-indicator with an identifier-or-keyword whose value does not equal `default` is implementation-defined. An implementation that does not recognize such an identifier-or-keyword in a line-indicator shall issue a warning.

[Note: Note that a file-name differs from a regular string literal in that escape characters are not processed; the \ character simply designates an ordinary back-slash character within a file-name. end note]

### 9.5.8 Pragma directives

The `#pragma` directive is a preprocessing directive used to specify contextual information to a compiler.

[Note: For example, a compiler might provide `#pragma` directives that

- Enable or disable particular warning messages when compiling subsequent code.
- Specify which optimizations to apply to subsequent code.
- Specify information to be used by a debugger.

end note]
10. Basic concepts

10.1 Application startup

*Application startup* occurs when the execution environment calls a designated method, which is referred to as the application's *entry point*. This entry point method is always named `Main`, and shall have one of the following signatures:

```csharp
static void Main() { .. }
static void Main(string[] args) { .. }
static int Main() { .. }
static int Main(string[] args) { .. }
```

As shown, the entry point can optionally return an `int` value. This return value is used in application termination (§10.2).

The entry point can optionally have one formal parameter, and this formal parameter can have any name. If such a parameter is declared, it shall obey the following constraints:

- The implementation shall ensure that the value of this parameter is not `null`.
- Let `args` be the name of the parameter. If the length of the array designated by `args` is greater than zero, the array members `args[0]` through `args[args.Length-1]`, inclusive, shall refer to strings, called *application parameters*, which are given implementation-defined values by the host environment prior to application startup. The intent is to supply to the application information determined prior to application startup from elsewhere in the hosted environment. If the host environment is not capable of supplying strings with letters in both uppercase and lowercase, the implementation shall ensure that the strings are received in lowercase. [Note: On systems supporting a command line, application parameters correspond to what are generally known as command-line arguments. end note]

Since C# supports method overloading, a class or struct can contain multiple definitions of some method, provided each has a different signature. However, within a single program, no class or struct shall contain more than one method called `Main` whose definition qualifies it to be used as an application entry point. Other overloaded versions of `Main` are permitted, however, provided they have more than one parameter, or their only parameter is other than type `string[]`.

An application can be made up of multiple classes or structs. It is possible for more than one of these classes or structs to contain a method called `Main` whose definition qualifies it to be used as an application entry point. In such cases, one of these `Main` methods shall be chosen as the entry point so that application startup can occur. This choice of an entry point is beyond the scope of this specification—no mechanism for specifying or determining an entry point is provided.

In C#, every method shall be defined as a member of a class or struct. Ordinarily, the declared accessibility (§10.5.1) of a method is determined by the access modifiers (§17.2.3) specified in its declaration, and similarly the declared accessibility of a type is determined by the access modifiers specified in its declaration. In order for a given method of a given type to be callable, both the type and the member shall be accessible. However, the application entry point is a special case. Specifically, the execution environment can access the application's entry point regardless of its declared accessibility and regardless of the declared accessibility of its enclosing type declarations.

The entry point method shall not be defined in a generic class declaration (§25.1) or a generic struct declaration (§25.2).

In all other respects, entry point methods behave like those that are not entry points.
10.2 Application termination

Application termination returns control to the execution environment.

If the return type of the application’s entry point method is `int`, the value returned serves as the application's termination status code. The purpose of this code is to allow communication of success or failure to the execution environment.

If the return type of the entry point method is `void`, reaching the right brace (`{`) which terminates that method, or executing a `return` statement that has no expression, results in a termination status code of 0.

Prior to an application’s termination, finalizers for all of its objects that have not yet been garbage collected are called, unless such cleanup has been suppressed (by a call to the library method `GC.SuppressFinalize`, for example).

10.3 Declarations

Declarations in a C# program define the constituent elements of the program. C# programs are organized using namespace declarations (§16), which can contain type declarations and nested namespace declarations. Type declarations (§16.6) are used to define classes (§17), structs (§18), interfaces (§20), enums (§21), and delegates (§22). The kinds of members permitted in a type declaration depend on the form of the type declaration. For instance, class declarations can contain declarations for constants (§17.3), fields (§17.4), methods (§17.5), properties (§17.6), events (§17.7), indexers (§17.8), operators (§17.9), instance constructors (§17.10), finalizers (§17.12), static constructors (§17.11), and nested types.

A declaration defines a name in the declaration space to which the declaration belongs. It is a compile-time error to have two or more declarations that introduce members with the same name in a declaration space, except in the following cases:

- Two or more namespace declarations with the same name are allowed in the same declaration space. Such namespace declarations are aggregated to form a single logical namespace and share a single declaration space.
- Declarations in separate programs but in the same namespace declaration space are allowed to share the same name.
- Two or more methods with the same name but distinct signatures are allowed in the same declaration space (§10.6).
- Two or more type declarations with the same name but distinct numbers of type parameters are allowed in the same declaration space (§10.8.2).
- Two or more type declarations with the `partial` modifier in the same declaration space may share the same name, same number of type parameters and same classification (class, struct or interface). In this case, the type declarations contribute to a single type and are themselves aggregated to form a single declaration space (§17.14).
- A namespace declaration and one or more type declarations in the same declaration space may share the same name as long as the type declarations all have at least one type parameter (§10.8.2).

It is never possible for a type declaration space to contain different kinds of members with the same name. [Example: A type declaration space can never contain a field and a method by the same name. end example]

There are several different types of declaration spaces, as described in the following.

- Within all source files of a program, `namespace-member-declarations` with no enclosing `namespace-declaration` are members of a single combined declaration space called the global declaration space.
- Within all source files of a program, `namespace-member-declarations` within `namespace-declarations` that have the same fully qualified namespace name are members of a single combined declaration space.
• Each compilation-unit and namespace-body has an alias declaration space. Each extern-alias-directive and using-alias-directive of the compilation-unit or namespace-body contributes a member to the alias declaration space (§16.4.1).

• Each non-partial class, struct, or interface declaration creates a new declaration space. Each partial class, struct, or interface declaration contributes to a declaration space shared by all matching parts in the same program (§17.1.4). Names are introduced into this declaration space through the type-parameter-list and class-member-declarations, struct-member-declarations, or interface-member-declarations. Except for overloaded instance constructor declarations and static constructor declarations, a class or struct member declaration cannot introduce a member by the same name as the class or struct. A class, struct, or interface permits the declaration of overloaded methods and indexers. Furthermore, a class or struct permits the declaration of overloaded instance constructors, operators, and types. [Example: A class, struct, or interface can contain multiple method declarations with the same name, provided these method declarations differ in their signature (§10.6). A class or struct can contain multiple nested types with the same name provided the types differ in the number of type parameters. end example] Base classes do not contribute to the declaration space of a class, and base interfaces do not contribute to the declaration space of an interface. Thus, a derived class or interface is allowed to declare a member with the same name as an inherited member.

• Each enumeration declaration creates a new declaration space. Names are introduced into this declaration space through enum-member-declarations.

• Each block or switch-block creates a declaration space for local variables and local constants called the local variable declaration space. Names are introduced into this declaration space through local-variable-declarations and local-constant-declarations. If a block is the body of an instance constructor, method, or operator declaration, or a get or set accessor for an indexer declaration, the parameters declared in such a declaration are members of the block’s local variable declaration space. If a block is the body of a generic method, the type parameters declared in such a declaration are members of the block’s local variable declaration space. It is an error for two members of a local variable declaration space to have the same name. It is an error for the local variable declaration space of a block and the local variable declaration space of a nested block to contain elements with the same name. [Note: Thus, within a nested block it is not possible to declare a local variable or constant with the same name as a local variable or constant in an enclosing block. It is possible for two nested blocks to contain elements with the same name as long as neither block contains the other. end note]

• Each block or switch-block creates a separate declaration space for labels called the label declaration space of the block. Names are introduced into this declaration space through labeled-statements, and the names are referenced through goto-statements. It is an error for the label declaration space of a block and the label declaration space of a nested block to contain elements with the same name. Thus, within a nested block it is not possible to declare a label with the same name as a label in an enclosing block. [Note: It is possible for two nested blocks to contain elements with the same name as long as neither block contains the other. end note]

The textual order in which names are declared is generally of no significance. In particular, textual order is not significant for the declaration and use of namespaces, constants, methods, properties, events, indexers, operators, instance constructors, finalizers, static constructors, and types. Declaration order is significant in the following ways:

• Declaration order for field declarations and local variable declarations determines the order in which their initializers (if any) are executed. When there are field declarations in multiple partial type declarations for the same type, the order of the parts is unspecified. However, within each part the field initializers are executed in order.

• Local variables and local constants shall be defined before they are used (§10.7).

• Declaration order for enum member declarations (§21.3) is significant when constant-expression values are omitted.
[Example: The declaration space of a namespace is “open ended”, and two namespace declarations with the same fully qualified name contribute to the same declaration space. For example

```csharp
namespace Megacorp.Data
{
    class Customer
    {
    }
}
namespace Megacorp.Data
{
    class Order
    {
    }
}
```

The two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `Megacorp.Data.Customer` and `Megacorp.Data.Order`. Because the two declarations contribute to the same declaration space, it would have caused a compile-time error if each contained a declaration of a class with the same name.

All declarations of a partial type contribute to the same declaration space:

```csharp
partial class C
{
    int F;
    partial struct N1 {...}
    partial class N2 {...}
    partial class N3 {...}
}
partial class C
{
    void F() {...}  // Error: conflicts with field F
    partial class N1 {...} // Error: conflicts with struct N1
    class N2 {...}  // Error: conflicts with other N2
    partial class N3 {...} // Ok
}
```

The two partial declarations for `C` combine to form a single declaration space and a single type. The field named `F` in the first part conflicts with the method named `F` in the second part. The struct named `N1` in the first part conflicts with the class named `N1` in the second part. The non-partial class `N2` in the second part conflicts with the partial class `N2` in the first part. The two partial declarations for `N3` combine to form a single type `C.N3`.

[Note: As specified above, the declaration space of a block cannot share names with the declaration spaces of any nested blocks. Thus, in the following example, the `F` and `G` methods result in a compile-time error because the name `i` is declared in the outer block and cannot be redeclared in the inner block. However, the `H` and `I` methods are valid since the two `i`’s are declared in separate non-nested blocks.

```csharp
class A
{
    void F() {
        int i = 0;
        if (true) {
            int i = 1;
        }
    }
    void G() {
        if (true) {
            int i = 0;
        } int i = 1;
    }
}
```
```csharp
void H() {
    if (true) {
        int i = 0;
    }
    if (true) {
        int i = 1;
    }
}
void I() {
    for (int i = 0; i < 10; i++)
        H();
    for (int i = 0; i < 10; i++)
        H();
}
```

### 10.4 Members

Namespaces and types have *members*. [Note: The members of an entity are generally available through the use of a qualified name that starts with a reference to the entity, followed by a “.” token, followed by the name of the member. *end note*]

Members of a type are either declared in the type or *inherited* from the base class of the type. When a type inherits from a base class, all members of the base class, except instance constructors, finalizers, and static constructors become members of the derived type. The declared accessibility of a base class member does not control whether the member is inherited—inheritance extends to any member that isn’t an instance constructor, static constructor, or finalizer. However, an inherited member might not be accessible in a derived type, either because of its declared accessibility (§10.5.1) or because it is hidden by a declaration in the type itself (§10.7.1.2).

#### 10.4.1 Namespace members

Namespaces and types that have no enclosing namespace are members of the *global namespace*. This corresponds directly to the names declared in the global declaration space.

Namespaces and types declared within a namespace are members of that namespace. This corresponds directly to the names declared in the declaration space of the namespace.

Namespaces have no access restrictions. It is not possible to declare private, protected, or internal namespaces, and namespace names are always publicly accessible.

#### 10.4.2 Struct members

The members of a struct are the members declared in the struct and the members inherited from the struct’s direct base class *System.ValueType* and the indirect base class *object*.

The members of a simple type are the members of the struct type aliased by the simple type (§11.1.4).

#### 10.4.3 Enumeration members

The members of an enumeration are the constants declared in the enumeration and the members inherited from the enumeration’s direct base class *System.Enum* and the indirect base classes *System.ValueType* and *object*.

#### 10.4.4 Class members

The members of a class are the members declared in the class and the members inherited from the base class (except for class *object* which has no base class). The members inherited from the base class include the constants, fields, methods, properties, events, indexers, operators, and types of the base class, but not the instance constructors, finalizers, and static constructors of the base class. Base class members are inherited without regard to their accessibility.
A class declaration can contain declarations of constants, fields, methods, properties, events, indexers, operators, instance constructors, finalizers, static constructors, and types.

The members of `object` and `string` correspond directly to the members of the class types they alias:

- The members of `object` are the members of the `System.Object` class.
- The members of `string` are the members of the `System.String` class.

### 10.4.5 Interface members

The members of an interface are the members declared in the interface and in all base interfaces of the interface. [Note: The members in class `object` are not, strictly speaking, members of any interface (§20.2). However, the members in class `object` are available via member lookup in any interface type (§14.3). end note]

### 10.4.6 Array members

The members of an array are the members inherited from class `System.Array`.

### 10.4.7 Delegate members

The members of a delegate are the members inherited from class `System.Delegate`.

### 10.5 Member access

Declarations of members allow control over member access. The accessibility of a member is established by the declared accessibility (§10.5.1) of the member combined with the accessibility of the immediately containing type, if any.

When access to a particular member is allowed, the member is said to be **accessible**. Conversely, when access to a particular member is disallowed, the member is said to be **inaccessible**. Access to a member is permitted when the textual location in which the access takes place is included in the accessibility domain (§10.5.2) of the member.

#### 10.5.1 Declared accessibility

The **declared accessibility** of a member can be one of the following:

- **Public**, which is selected by including a `public` modifier in the member declaration. The intuitive meaning of `public` is “access not limited”.
- **Protected**, which is selected by including a `protected` modifier in the member declaration. The intuitive meaning of `protected` is “access limited to the containing class or types derived from the containing class”.
- **Internal**, which is selected by including an `internal` modifier in the member declaration. The intuitive meaning of `internal` is “access limited to this program”.
- **Protected internal**, which is selected by including both a `protected` and an `internal` modifier in the member declaration. The intuitive meaning of `protected internal` is “access limited to this program or types derived from the containing class”.
- **Private**, which is selected by including a `private` modifier in the member declaration. The intuitive meaning of `private` is “access limited to the containing type”.

Depending on the context in which a member declaration takes place, only certain types of declared accessibility are permitted. Furthermore, when a member declaration does not include any access modifiers, the context in which the declaration takes place determines the default declared accessibility.

- Namespaces implicitly have `public` declared accessibility. No access modifiers are allowed on namespace declarations.
• Types declared in compilation units or namespaces can have public or internal declared accessibility and default to internal declared accessibility.

• Class members can have any of the five kinds of declared accessibility and default to private declared accessibility. [Note: A type declared as a member of a class can have any of the five kinds of declared accessibility, whereas a type declared as a member of a namespace can have only public or internal declared accessibility. end note]

• Struct members can have public, internal, or private declared accessibility and default to private declared accessibility because structs are implicitly sealed. Struct members introduced in a struct (that is, not inherited by that struct) cannot have protected or protected internal declared accessibility. [Note: A type declared as a member of a struct can have public, internal, or private declared accessibility, whereas a type declared as a member of a namespace can have only public or internal declared accessibility. end note]

• Interface members implicitly have public declared accessibility. No access modifiers are allowed on interface member declarations.

• Enumeration members implicitly have public declared accessibility. No access modifiers are allowed on enumeration member declarations.

10.5.2 Accessibility domains

The accessibility domain of a member consists of the (possibly disjoint) sections of program text in which access to the member is permitted. For purposes of defining the accessibility domain of a member, a member is said to be top-level if it is not declared within a type, and a member is said to be nested if it is declared within another type. Furthermore, the text of a program is defined as all source text contained in all source files of that program, and the source text of a type is defined as all source text contained between the opening and closing “{” and “}” tokens in the class-body, struct-body, interface-body, or enum-body of all declarations for the type (including, possibly, multiple partial declarations and all types that are nested within the type).

The accessibility domain of a predefined type (such as object, int, or double) is unlimited.

The accessibility domain of a top-level type \( T \) that is declared in a program \( P \) is defined as follows:

• If the declared accessibility of \( T \) is public, the accessibility domain of \( T \) is the program text of \( P \) and any program that references \( P \).

• If the declared accessibility of \( T \) is internal, the accessibility domain of \( T \) is the program text of \( P \).

[Note: From these definitions, it follows that the accessibility domain of a top-level type is always at least the program text of the program in which that type is declared. end note]

The accessibility domain of a nested member \( M \) declared in a type \( T \) within a program \( P \), is defined as follows (noting that \( M \) itself might possibly be a type):

• If the declared accessibility of \( M \) is public, the accessibility domain of \( M \) is the accessibility domain of \( T \).

• If the declared accessibility of \( M \) is protected internal, let \( D \) be the union of the program text of \( P \) and the program text of any type derived from \( T \), which is declared outside \( P \). The accessibility domain of \( M \) is the intersection of the accessibility domain of \( T \) with \( D \).

• If the declared accessibility of \( M \) is protected, let \( D \) be the union of the program text of \( T \) and the program text of any type derived from \( T \). The accessibility domain of \( M \) is the intersection of the accessibility domain of \( T \) with \( D \).

• If the declared accessibility of \( M \) is internal, the accessibility domain of \( M \) is the intersection of the accessibility domain of \( T \) with the program text of \( P \).

• If the declared accessibility of \( M \) is private, the accessibility domain of \( M \) is the program text of \( T \).
Note: From these definitions, it follows that the accessibility domain of a nested member is always at least the program text of the type in which the member is declared. Furthermore, it follows that the accessibility domain of a member is never more inclusive than the accessibility domain of the type in which the member is declared. end note

Note: In intuitive terms, when a type or member $M$ is accessed, the following steps are evaluated to ensure that the access is permitted:

- First, if $M$ is declared within a type (as opposed to a compilation unit or a namespace), a compile-time error occurs if that type is not accessible.
- Then, if $M$ is public, the access is permitted.
- Otherwise, if $M$ is protected internal, the access is permitted if it occurs within the program in which $M$ is declared, or if it occurs within a class derived from the class in which $M$ is declared and takes place through the derived class type (§10.5.3).
- Otherwise, if $M$ is protected, the access is permitted if it occurs within the class in which $M$ is declared, or if it occurs within a class derived from the class in which $M$ is declared and takes place through the derived class type (§10.5.3).
- Otherwise, if $M$ is internal, the access is permitted if it occurs within the program in which $M$ is declared.
- Otherwise, if $M$ is private, the access is permitted if it occurs within the type in which $M$ is declared.
- Otherwise, the type or member is inaccessible, and a compile-time error occurs.

end note

Example: In the following code

```csharp
public class A
{
    public static int X;
    internal static int Y;
    private static int Z;
}

internal class B
{
    public static int X;
    internal static int Y;
    private static int Z;
    public class C
    {
        public static int X;
        internal static int Y;
        private static int Z;
    }
    private class D
    {
        public static int X;
        internal static int Y;
        private static int Z;
    }
}
```

the classes and members have the following accessibility domains:

- The accessibility domain of A and A.X is unlimited.
- The accessibility domain of A.Y, B.X, B.Y, B.C, B.C.X, and B.C.Y is the program text of the containing program.
- The accessibility domain of A.Z is the program text of A.
The accessibility domain of B.Z and B.D is the program text of B, including the program text of B.C and B.D.

The accessibility domain of B.C.Z is the program text of B.C.

The accessibility domain of B.D.X and B.D.Y is the program text of B, including the program text of B.C and B.D.

The accessibility domain of B.D.Z is the program text of B.D.

As the example illustrates, the accessibility domain of a member is never larger than that of a containing type. For example, even though all X members have public declared accessibility, all but A.X have accessibility domains that are constrained by a containing type. end example

As described in §10.4, all members of a base class, except for instance constructors, finalizers, and static constructors are inherited by derived types. This includes even private members of a base class. However, the accessibility domain of a private member includes only the program text of the type in which the member is declared. [Example: In the following code

```java
class A {
    int x;
    static void F(B b) {
        b.x = 1;  // Ok
    }
}
class B: A {
    static void F(B b) {
        b.x = 1;  // Error, x not accessible
    }
}
```

the B class inherits the private member x from the A class. Because the member is private, it is only accessible within the class-body of A. Thus, the access to b.x succeeds in the A.F method, but fails in the B.F method. end example]

10.5.3 Protected access for instance members

When a protected instance member is accessed outside the program text of the class in which it is declared, and when a protected internal instance member is accessed outside the program text of the program in which it is declared, the access is required to take place through an instance of the derived class type in which the access occurs. Let B be a base class that declares a protected instance member M, and let D be a class that derives from B. Within the class-body of D, access to M can take one of the following forms:

- An unqualified type-name or primary-expression of the form M.
- A primary-expression of the form E.M, provided the type of E is D or a class derived from D.
- A primary-expression of the form base.M.

In addition to these forms of access, a derived class can access a protected instance constructor of a base class in a constructor-initializer ($\S$17.10.1).

[Example: In the following code

```java
public class A {
    protected int x;
    static void F(A a, B b) {
        a.x = 1;  // Ok
        b.x = 1;  // Ok
    }
}
```
C# LANGUAGE SPECIFICATION

```csharp
public class B: A
{
    static void F(A a, B b) {
        a.x = 1; // Error, must access through instance of B
        b.x = 1; // Ok
    }
}
```

within A, it is possible to access x through instances of both A and B, since in either case the access takes place through an instance of A or a class derived from A. However, within B, it is not possible to access x through an instance of A, since A does not derive from B. end example]

In the context of generics (§25.1.6), the rules for accessing protected and protected internal instance members are augmented by the following:

- Within a generic class G, access to an inherited protected instance member M using a `primary-expression` of the form E.M is permitted if the type of E is a class type constructed from G or a class type derived from a class type constructed from G.

10.5.4 Accessibility constraints

Several constructs in the C# language require a type to be at least as accessible as a member or another type. A type T is said to be at least as accessible as a member or type M if the accessibility domain of T is a superset of the accessibility domain of M. In other words, T is at least as accessible as M if T is accessible in all contexts in which M is accessible.

The following accessibility constraints exist:

- The direct base class of a class type shall be at least as accessible as the class type itself.
- The explicit base interfaces of an interface type shall be at least as accessible as the interface type itself.
- The return type and parameter types of a delegate type shall be at least as accessible as the delegate type itself.
- The type of a constant shall be at least as accessible as the constant itself.
- The type of a field shall be at least as accessible as the field itself.
- The return type and parameter types of a method shall be at least as accessible as the method itself.
- The type of a property shall be at least as accessible as the property itself.
- The type of an event shall be at least as accessible as the event itself.
- The type and parameter types of an indexer shall be at least as accessible as the indexer itself.
- The return type and parameter types of an operator shall be at least as accessible as the operator itself.
- The parameter types of an instance constructor shall be at least as accessible as the instance constructor itself.

[Example: In the following code
```csharp
class A {...}
public class B: A {...}
```
the B class results in a compile-time error because A is not at least as accessible as B. end example]

[Example: Likewise, in the following code
```csharp
class A {...}
public class B
{
    A F() {...}
    internal A G() {...}
```
public A H() {...}
}

the H method in B results in a compile-time error because the return type A is not at least as accessible as the method. end example]

10.6 Signatures and overloading

Methods, instance constructors, indexers, and operators are characterized by their signatures:

- The signature of a method consists of the name of the method, the number of type parameters, and the type and kind (value, reference, or output) of each of its formal parameters, considered in the order left to right. The signature of a method specifically does not include the return type, parameter names, or type parameter names, nor does it include the params modifier that can be specified for the right-most parameter. When a parameter type includes a type parameter of the method, the ordinal position of the type parameter is used for type equivalence, not the name of the type parameter.

- The signature of an instance constructor consists of the type and kind (value, reference, or output) of each of its formal parameters, considered in the order left to right. The signature of an instance constructor specifically does not include the parameter names or the params modifier that can be specified for the right-most parameter.

- The signature of an indexer consists of the type of each of its formal parameters, considered in the order left to right. The signature of an indexer specifically does not include the element type or parameter names, nor does it include the params modifier that can be specified for the right-most parameter.

- The signature of an operator consists of the name of the operator and the type of each of its formal parameters, considered in the order left to right. The signature of an operator specifically does not include the result type or parameter names.

Signatures are the enabling mechanism for overloading of members in classes, structs, and interfaces:

- Overloading of methods permits a class, struct, or interface to declare multiple methods with the same name, provided their signatures are unique within that class, struct, or interface.

- Overloading of instance constructors permits a class or struct to declare multiple instance constructors, provided their signatures are unique within that class or struct.

- Overloading of indexers permits a class, struct, or interface to declare multiple indexers, provided their signatures are unique within that class, struct, or interface.

- Overloading of operators permits a class or struct to declare multiple operators with the same name, provided their signatures are unique within that class or struct.

Although out and ref parameter modifiers are considered part of a signature, members declared in a single type cannot differ in signature solely by ref and out. A compile-time error occurs if two members are declared in the same type with signatures that would be the same if all parameters in both methods with out modifiers were changed to ref modifiers. For other purposes of signature matching (e.g., hiding or overriding), ref and out are considered part of the signature and do not match each other. [Note: This restriction is to allow C# programs to be easily translated to run on the Common Language Infrastructure (CLI), which does not provide a way to define methods that differ solely in ref and out. end note]

[Example: The following example shows a set of overloaded method declarations along with their signatures.

```csharp
interface ITest
{
    void F();       // F()
    void F(int x);      // F(int)
    void F(ref int x);    // F(ref int)
    void F(out int x);    // F(out int)    error
```
void F(int x, int y);  // F(int, int)
int F(string s);       // F(string)
int F(int x);         // F(int)       error
void F(string[] a);    // F(string[])
void F(params string[] a); // F(string[])  error
void F<S>(S s);        // F<`0>(`0)
void F<T>(T t);        // F<`0>(`0)       error
void F<S,T>(S s);      // F<`0,`1>(`0)
void F<T,S>(S s);      // F<`0,`1>(`1)    ok
}

Note that any ref and out parameter modifiers (§17.5.1) are part of a signature. Thus, F(int), F(ref int), and F(out int) are all unique signatures. However, F(ref int) and F(out int) cannot be declared within the same interface because their signatures differ solely by ref and out. Also, note that the return type and the params modifier are not part of a signature, so it is not possible to overload solely based on return type or on the inclusion or exclusion of the params modifier. As such, the declarations of the methods F(int) and F(params string[]) identified above, result in a compile-time error. end example]

10.7 Scopes

The scope of a name is the region of program text within which it is possible to refer to the entity declared by the name without qualification of the name. Scopes can be nested, and an inner scope can redefine the meaning of a name from an outer scope. [Note: This does not, however, remove the restriction imposed by §10.3 that within a nested block it is not possible to declare a local variable or local constant with the same name as a local variable or local constant in an enclosing block. end note] The name from the outer scope is then said to be hidden in the region of program text covered by the inner scope, and access to the outer name is only possible by qualifying the name.

- The scope of a namespace member declared by a namespace-member-declaration (§16.5) with no enclosing namespace-declaration is the entire program text.
- The scope of a namespace member declared by a namespace-member-declaration within a namespace-declaration whose fully qualified name is N, is the namespace-body of every namespace-declaration whose fully qualified name is N or starts with N, followed by a period.
- The scope of a name defined by an extern-alias-directive (§16.3) extends over the using-directives, global-attributes and namespace-member-declarations of the compilation-unit or namespace-body in which the extern-alias-directive occurs. An extern-alias-directive does not contribute any new members to the underlying declaration space. In other words, an extern-alias-directive is not transitive, but, rather, affects only the compilation-unit or namespace-body in which it occurs.
- The scope of a name defined or imported by a using-directive (§16.4) extends over the global-attributes and namespace-member-declarations of the compilation-unit or namespace-body in which the using-directive occurs. A using-directive can make zero or more namespace or type names available within a particular compilation-unit or namespace-body, but does not contribute any new members to the underlying declaration space. In other words, a using-directive is not transitive, but, rather, affects only the compilation-unit or namespace-body in which it occurs.
- The scope of a member declared by a class-member-declaration (§17.2) is the class-body in which the declaration occurs. In addition, the scope of a class member extends to the class-body of those derived classes that are included in the accessibility domain (§10.5.2) of the member.
- The scope of a member declared by a struct-member-declaration (§18.2) is the struct-body in which the declaration occurs.
- The scope of a member declared by an enum-member-declaration (§21.3) is the enum-body in which the declaration occurs.
- The scope of a parameter declared in a method-declaration (§17.5) is the method-body of that method-declaration.
The scope of a parameter declared in an indexer-declaration (§17.8) is the accessor-declarations of that indexer-declaration.

The scope of a parameter declared in an operator-declaration (§17.9) is the block of that operator-declaration.

The scope of a parameter declared in a constructor-declaration (§17.10) is the constructor-initializer and block of that constructor-declaration.

The scope of a label declared in a labeled-statement (§15.4) is the block in which the declaration occurs.

The scope of a local variable declared in a local-variable-declaration (§15.5.1) is the block in which the declaration occurs.

The scope of a local variable declared in a switch-block of a switch statement (§15.7.2) is the switch-block.

The scope of a local variable declared in a for-block of a for statement (§15.8.3) is the for-initializer, the for-condition, the for-iterator, and the contained statement of the for statement.

The scope of a local constant declared in a local-constant-declaration (§15.5.2) is the block in which the declaration occurs. It is a compile-time error to refer to a local constant in a textual position that precedes its constant-declarator.

Within the scope of a namespace, class, struct, or enumeration member it is possible to refer to the member in a textual position that precedes the declaration of the member. [Example:

```csharp
class A {
    void F() {
        i = 1;
        int i = 0;
    }
}
```

Here, it is valid for `F` to refer to `i` before it is declared. end example]

Within the scope of a local variable, it is a compile-time error to refer to the local variable in a textual position that precedes the declaration of the local variable. [Example:

```csharp
class A {
    int i = 0;
    void F() {
        i = 1;  // Error, use precedes declaration
        int i;
        i = 2;
    }
    void G() {
        int j = (j = 1);  // valid
    }
    void H() {
        int a = 1, b = ++a;  // valid
    }
}
```

In the `F` method above, the first assignment to `i` specifically does not refer to the field declared in the outer scope. Rather, it refers to the local variable and it results in a compile-time error because it textually precedes the declaration of the variable. In the `G` method, the use of `j` in the initializer for the declaration of `j` is valid because the use does not precede the local-variable-declarator. In the `H` method, a subsequent local-variable-declarator correctly refers to a local variable declared in an earlier local-variable-declarator within the same local-variable-declaration. end example]

[Note: The scoping rules for local variables and local constants are designed to guarantee that the meaning of a name used in an expression context is always the same within a block. If the scope of a local variable were
to extend only from its declaration to the end of the block, then in the example above, the first assignment would assign to the instance variable and the second assignment would assign to the local variable. (In certain situations, but not in the example above, this could lead to a compile-time error if the statements of the block were later to be rearranged.)

The meaning of a name within a block can differ based on the context in which the name is used. In the example

```csharp
using System;
class A {}

class Test
{
    static void Main()
    {
        string A = "hello, world"; // declarator context
        string s = A; // expression context
        Type t = typeof(A); // type context
        Console.WriteLine(s); // writes "hello, world"
        Console.WriteLine(t.ToString()); // writes "Type: A"
    }
}
```

the name `A` is used in an expression context to refer to the local variable `A` and in a type context to refer to the class `A`. [end note]

10.7.1 Name hiding

The scope of an entity typically encompasses more program text than the declaration space of the entity. In particular, the scope of an entity can include declarations that introduce new declaration spaces containing entities of the same name. Such declarations cause the original entity to become hidden. Conversely, an entity is said to be visible when it is not hidden.

Name hiding occurs when scopes overlap through nesting and when scopes overlap through inheritance. The characteristics of the two types of hiding are described in the following subclauses.

Local variables, local constants, parameters, and method type parameters cannot hide other local variables, local constants, parameters, or method type parameters (§10.3).

10.7.1.1 Hiding through nesting

Name hiding through nesting can occur as a result of nesting namespaces or types within namespaces, as a result of nesting types within classes or structs, and as a result of parameter, local variable, and local constant declarations. [Example: In the following code]

```csharp
class A
{
    int i = 0;
    void F()
    {
        int i = 1;
    }
    void G()
    {
        i = 1;
    }
}
```

within the `F` method, the instance variable `i` is hidden by the local variable `i`, but within the `G` method, `i` still refers to the instance variable. [end example]

When a name in an inner scope hides a name in an outer scope, it hides all overloaded occurrences of that name. [Example: In the following code]

```csharp
class Outer
{
    static void F(int i) {}
}
```
static void F(string s) {}
class Inner
{
    void G() {
        F(1);    // Invokes Outer.Inner.F
        F("Hello");  // Error
    }
    static void F(long l) {}
}

the call F(1) invokes the F declared in Inner because all outer occurrences of F are hidden by the inner declaration. For the same reason, the call F("Hello") results in a compile-time error. end example]

10.7.1.2 Hiding through inheritance
Name hiding through inheritance occurs when classes or structs redefine names that were inherited from base classes. This type of name hiding takes one of the following forms:

- A constant, field, property, or event introduced in a class or struct hides all base class members with the same name and no type parameters.
- A type introduced in a class or struct hides all base class members with the same name and same number of type parameters.
- A method introduced in a class or struct hides all non-method base class members with the same name and either, the same number of type parameters or no type parameters, and all base class methods with the same signature.
- An indexer introduced in a class or struct hides all base class indexers with the same signature (parameter count and types).

Contrary to hiding a name from an outer scope, hiding an accessible name from an inherited scope causes a warning to be reported. [Example: In the following code

```csharp
class Base
{
    public void F() {}
}
class Derived: Base
{
    public void F() {}  // Warning, hiding an inherited name
}
```

the declaration of F in Derived causes a warning to be reported. Hiding an inherited name is specifically not an error, since that would preclude separate evolution of base classes. For example, the above situation might have come about because a later version of Base introduced an F method that wasn't present in an earlier version of the class. Had the above situation been an error, then any change made to a base class in a separately versioned class library could potentially cause derived classes to become invalid. end example]

The warning caused by hiding an inherited name can be eliminated through use of the new modifier:

[Example:

```csharp
class Base
{
    public void F() {}
}
class Derived: Base
{
    new public void F() {}
}
```

The new modifier indicates that the F in Derived is “new”, and that it is indeed intended to hide the inherited member. end example]
A declaration of a new member hides an inherited member only within the scope of the new member. [Example:

```csharp
class Base
{
    public static void F() {}
}

class Derived: Base
{
    new private static void F() {}  // Hides Base.F in Derived only
}

class MoreDerived: Derived
{
    static void G() { F(); }      // Invokes Base.F
}
```

In the example above, the declaration of `F` in `Derived` hides the `F` that was inherited from `Base`, but since the new `F` in `Derived` has private access, its scope does not extend to `MoreDerived`. Thus, the call `F()` in `MoreDerived.G` is valid and will invoke `Base.F`. end example]

### 10.8 Namespace and type names

Several contexts in a C# program require a `namespace-name` or a `type-name` to be specified.

- `namespace-name:
  namespace-or-type-name`
- `type-name:
  namespace-or-type-name`

A `namespace-name` is a `namespace-or-type-name` that refers to a namespace. Following resolution as described below, the `namespace-or-type-name` of a `namespace-name` shall refer to a namespace, or otherwise a compile-time error occurs. Type arguments (§25.5.1) shall not be present in a `namespace-name` (only types can have type arguments).

A `type-name` is a `namespace-or-type-name` that refers to a type. Following resolution as described below, the `namespace-or-type-name` of a `type-name` shall refer to a type, or otherwise a compile-time error occurs.

The syntax and semantics of `qualified-alias-member` are defined in §16.7.

A `namespace-or-type-name` that is not a `qualified-alias-member` has one of four forms:

- `I`
- `I<A1, ..., Ak>`
- `N.I`
- `N.I<A1, ..., Ak>`

where `I` is a single identifier, `N` is a `namespace-or-type-name` and `<A1, ..., Ak>` is an optional `type-argument-list`. When no `type-argument-list` is specified, consider `K` to be zero.

The meaning of a `namespace-or-type-name` is determined as follows:

- If the `namespace-or-type-name` is a `qualified-alias-member`, the meaning is as specified in §16.7.
- Otherwise, if the `namespace-or-type-name` is of the form `I` or of the form `I<A1, ..., Ak>`:
If $K$ is zero and the *namespace-or-type-name* appears within the body of a generic method declaration (§25.6) and if that declaration includes a type parameter (§25.1.1) with name $I$, then the *namespace-or-type-name* refers to that type parameter.

Otherwise, if the *namespace-or-type-name* appears within the body of a type declaration, then for each instance type $T$ (§25.1.2), starting with the instance type of that type declaration and continuing with the instance type of each enclosing class or struct declaration (if any):

- If $K$ is zero and the declaration of $T$ includes a type parameter with name $I$, then the *namespace-or-type-name* refers to that type parameter.
- Otherwise, if $T$ contains a nested accessible type having name $I$ and $K$ type parameters, then the *namespace-or-type-name* refers to that type constructed with the given type arguments. If there is more than one such type, the type declared within the more derived type is selected. [Note: Non-type members (constants, fields, methods, properties, indexers, operators, instance constructors, finalizers, and static constructors) and type members with a different number of type parameters are ignored when determining the meaning of the *namespace-or-type-name*. end note]

Otherwise, for each namespace $N$, starting with the namespace in which the *namespace-or-type-name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:

- If $K$ is zero and $I$ is the name of a namespace in $N$, then:
  - If the location where the *namespace-or-type-name* occurs is enclosed by a namespace declaration for $N$ and the namespace declaration contains an *extern-alias-directive* or *using-alias-directive* that associates the name $I$ with a namespace or type, then the *namespace-or-type-name* is ambiguous and a compile-time error occurs.
  - Otherwise, the *namespace-or-type-name* refers to the namespace named $I$ in $N$.
- Otherwise, if $N$ contains an accessible type having name $I$ and $K$ type parameters, then:
  - If $K$ is zero and the location where the *namespace-or-type-name* occurs is enclosed by a namespace declaration for $N$ and the namespace declaration contains an *extern-alias-directive* or *using-alias-directive* that associates the name $I$ with a namespace or type, then the *namespace-or-type-name* is ambiguous and a compile-time error occurs.
  - Otherwise, the *namespace-or-type-name* refers to the type constructed with the given type arguments.
- Otherwise, if the location where the *namespace-or-type-name* occurs is enclosed by a namespace declaration for $N$:
  - If $K$ is zero and the namespace declaration contains an *extern-alias-directive* or *using-alias-directive* that associates the name $I$ with an imported namespace or type, then the *namespace-or-type-name* refers to that namespace or type.
  - Otherwise, if the namespaces imported by the *using-namespaces-directives* of the namespace declaration contain exactly one type having name $I$ and $K$ type parameters, then the *namespace-or-type-name* refers to that type constructed with the given type arguments.
  - Otherwise, if the namespaces imported by the *using-namespaces-directives* of the namespace declaration contain more than one type having name $I$ and $K$ type parameters, then the *namespace-or-type-name* is ambiguous and an error occurs.
- Otherwise, the *namespace-or-type-name* is undefined and a compile-time error occurs.

- Otherwise, the *namespace-or-type-name* is of the form $N.I$ or of the form $N.I<A_1, ..., A_k>$. $N$ is first resolved as a *namespace-or-type-name*. If the resolution of $N$ is not successful, a compile-time error occurs. Otherwise, $N.I$ or $N.I<A_1, ..., A_k>$ is resolved as follows:
If $K$ is zero and $N$ refers to a namespace and $N$ contains a nested namespace with name $I$, then the

```
namespace-or-type-name
```

refers to that nested namespace.

Otherwise, if $N$ refers to a namespace and $N$ contains an accessible type having name $I$ and $K$ type

parameters, then the `namespace-or-type-name` refers to that type constructed with the given type

arguments.

Otherwise, if $N$ refers to a (possibly constructed) class or struct type and $N$ contains a nested

accessible type having name $I$ and $K$ type parameters, then the `namespace-or-type-name` refers to

that type constructed with the given type arguments. If there is more than one such type, the type

declared within the more derived type is selected.

Otherwise, $N.I$ is an invalid `namespace-or-type-name`, and a compile-time error occurs.

A `namespace-or-type-name` is permitted to reference a static class (§17.1.1.3) if

- The `namespace-or-type-name` is the $T$ in a `namespace-or-type-name` of the form $T.I$, or
- The `namespace-or-type-name` is the $T$ in a `typeof-expression` (§14.5.11) of the form `typeof(T)`

### 10.8.1 Unqualified name

Every namespace declaration and type declaration has an `unqualified name` determined as follows:

- For a namespace declaration, the unqualified name is the `qualified-identifier` specified in the declaration.
- For a type declaration with no `type-parameter-list`, the unqualified name is the `identifier` specified in the
  declaration.
- For a type declaration with $K$ type parameters, the unqualified name is the `identifier` specified in the
  declaration, followed by the `< token, $K-1$ commas and the > token.

### 10.8.2 Fully qualified names

Every namespace declaration and type declaration has a `fully qualified name`, which uniquely identifies the

namespace or type amongst all others. The fully qualified name of a namespace or type declaration with

unqualified name $N$ is determined as follows:

- If the declaration is contained directly in a compilation unit and not nested in any other declaration, its
  fully qualified name is $N$.
- Otherwise, its fully qualified name is $S.N$, where $S$ is the fully qualified name of the immediately
  enclosing namespace or type declaration.

In other words, the fully qualified name of a declaration is the complete hierarchical path of identifiers (and

generic dimensionality specifiers) that lead to the type or namespace, starting from the global namespace.
The fully qualified name of a declaration shall uniquely identify the namespace, non-generic type or generic

instance type (§25.1.2) associated with the declaration. It is a compile-time error for the same fully qualified

name to refer to two distinct entities. In particular:

- It is an error for both a namespace declaration and a type declaration to have the same fully qualified
  name.
- It is an error for two different kinds of type declarations to have the same fully qualified name (for
  example, if both a struct and class declaration have the same fully qualified name).
- It is an error for a type declaration without the `partial` modifier to have the same fully qualified name
  as another type declaration (§17.1.4).

[Example: The example below shows several namespace and type declarations along with their associated

fully qualified names.

```
class A {}                      // A
```
namespace X    // X
{
    class B    // X.B
    {
        class C {}  // X.B.C
    }
    namespace Y   // X.Y
    {
        class D {}  // X.Y.D
    }
}
namespace X.Y   // X.Y
{
    class E {}   // X.Y.E
    class G<T> {  // X.Y.G<> 
        class H {}  // X.Y.G<> .H
    }
    class G<S,T> {  // X.Y.G<,> 
        class H<U> {} // X.Y.G<,> .H<> 
    }
} 

end example

10.9 Automatic memory management

C# employs automatic memory management, which frees developers from manually allocating and freeing the memory occupied by objects. Automatic memory management policies are implemented by a garbage collector. The memory management life cycle of an object is as follows:

1. When the object is created, memory is allocated for it, the constructor is run, and the object is considered live.

2. If no part of the object can be accessed by any possible continuation of execution, other than the running of finalizers, the object is considered no longer in use and it becomes eligible for finalization. [Note: Implementations might choose to analyze code to determine which references to an object can be used in the future. For instance, if a local variable that is in scope is the only existing reference to an object, but that local variable is never referred to in any possible continuation of execution from the current execution point in the procedure, an implementation might (but is not required to) treat the object as no longer in use. end note]

3. Once the object is eligible for finalization, at some unspecified later time the finalizer (§17.12) (if any) for the object is run. Unless overridden by explicit calls, the finalizer for the object is run once only.

4. Once the finalizer for an object is run, if that object, or any part of it, cannot be accessed by any possible continuation of execution, including the running of finalizers, the object is considered inaccessible and the object becomes eligible for collection.

5. Finally, at some time after the object becomes eligible for collection, the garbage collector frees the memory associated with that object.

The garbage collector maintains information about object usage, and uses this information to make memory management decisions, such as where in memory to locate a newly created object, when to relocate an object, and when an object is no longer in use or inaccessible.

Like other languages that assume the existence of a garbage collector, C# is designed so that the garbage collector can implement a wide range of memory management policies. For instance, C# does not require that finalizers be run or that objects be collected as soon as they are eligible, or that finalizers be run in any particular order, or on any particular thread.

The behavior of the garbage collector can be controlled, to some degree, via static methods on the class System.GC.
Example: Since the garbage collector is allowed wide latitude in deciding when to collect objects and run finalizers, a conforming implementation might produce output that differs from that shown by the following code. The program

```csharp
using System;
class A
{
    ~A() {
        Console.WriteLine("Finalize instance of A");
    }
}

class B
{
    object Ref;
    public B(object o) {
        Ref = o;
    }
    ~B() {
        Console.WriteLine("Finalize instance of B");
    }
}

class Test
{
    static void Main() {
        B b = new B(new A());
        b = null;
        GC.Collect();
        GC.WaitForPendingFinalizers();
    }
}
```

creates an instance of class A and an instance of class B. These objects become eligible for garbage collection when the variable b is assigned the value null, since after this time it is impossible for any user-written code to access them. The output could be either

```
Finalize instance of A
Finalize instance of B
```
or

```
Finalize instance of B
Finalize instance of A
```
because the language imposes no constraints on the order in which objects are garbage collected.

In subtle cases, the distinction between “eligible for finalization” and “eligible for collection” can be important. For example,

```csharp
using System;
class A
{
    ~A() {
        Console.WriteLine("Finalize instance of A");
    }
    public void F() {
        Console.WriteLine("A.F");
        Test.RefA = this;
    }
}

class B
{
    public A Ref;
    ~B() {
        Console.WriteLine("Finalize instance of B");
        Ref.F();
    }
}
```
class Test
{
    public static A RefA;
    public static B RefB;
    static void Main()
    {
        RefB = new B();
        RefA = new A();
        RefB.Ref = RefA;
        RefB = null;
        RefA = null;
        // A and B now eligible for finalization
        GC.Collect();
        GC.WaitForPendingFinalizers();
        // B now eligible for collection, but A is not
        if (RefA != null)
            Console.WriteLine("RefA is not null");
    }
}

In the above program, if the garbage collector chooses to run the finalizer of A before the finalizer of B, then the output of this program might be:

Finalize instance of A
Finalize instance of B
A.F
RefA is not null

Note that although the instance of A was not in use and A's finalizer was run, it is still possible for methods of A (in this case, F) to be called from another finalizer. Also, note that running of a finalizer might cause an object to become usable from the mainline program again. In this case, the running of B's finalizer caused an instance of A that was previously not in use, to become accessible from the live reference RefA. After the call to WaitForPendingFinalizers, the instance of B is eligible for collection, but the instance of A is not, because of the reference RefA.

To avoid confusion and unexpected behavior, it is generally a good idea for finalizers to perform cleanup only on data stored in their object's own fields, and not to perform any actions on referenced objects or static fields. end example

10.10 Execution order
Execution shall proceed such that the side effects of each executing thread are preserved at critical execution points. A side effect is defined as a read or write of a volatile field, a write to a non-volatile variable, a write to an external resource, and the throwing of an exception. The critical execution points at which the order of these side effects shall be preserved are references to volatile fields (§17.4.3), lock statements (§15.12), and thread creation and termination. An implementation is free to change the order of execution of a C# program, subject to the following constraints:

- Data dependence is preserved within a thread of execution. That is, the value of each variable is computed as if all statements in the thread were executed in original program order.
- Initialization ordering rules are preserved (§17.4.4, §17.4.5).
- The ordering of side effects is preserved with respect to volatile reads and writes (§17.4.3). Additionally, an implementation need not evaluate part of an expression if it can deduce that that expression’s value is not used and that no needed side effects are produced (including any caused by calling a method or accessing a volatile field). When program execution is interrupted by an asynchronous event (such as an exception thrown by another thread), it is not guaranteed that the observable side effects are visible in the original program order.
11. Types

The types of the C# language are divided into three main categories: Value types, reference types, and type-parameter types.

```
type:
  value-type
  reference-type
  type-parameter
```

Type parameters are part of generics, and are discussed in §25.1.1. A fourth category of types, pointers, is available only in unsafe code. This is discussed further in §27.2.

Value types differ from reference types in that variables of the value types directly contain their data, whereas variables of the reference types store references to their data, the latter being known as objects. With reference types, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With value types, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other.

[Note: When a variable is a ref or out parameter, it does not have its own storage but references the storage of another variable. In this case, the ref or out variable is effectively an alias for another variable and not a distinct variable. end note]

C#’s type system is unified such that a value of any type can be treated as an object. Every type in C# directly or indirectly derives from the object class type, and object is the ultimate base class of all types. Values of reference types are treated as objects simply by viewing the values as type object. Values of value types are treated as objects by performing boxing and unboxing operations (§11.3).

11.1 Value types

A value type is either a struct type or an enumeration type. C# provides a set of predefined struct types called the simple types. The simple types are identified through reserved words.

```
value-type:
  struct-type
  enum-type

struct-type:
  type-name
  simple-type
  nullable-type

simple-type:
  numeric-type
  bool

numeric-type:
  integral-type
  floating-point-type
  decimal
```
integral-type:
  sbyte
  byte
  short
  ushort
  int
  uint
  long
  ulong
  char

floating-point-type:
  float
  double

enum-type:
  type-name

nullable-type:
  non-nullable-value-type

non-nullable-value-type:
  enum-type
  type-name
  simple-type

All value types implicitly inherit from class `Object`. It is not possible for any type to derive from a value type, and value types are thus implicitly sealed (§17.1.1.2).

A variable of a value type always contains a value of that type. Unlike reference types, it is not possible for a value of a value type to be `null`, or to reference an object of a more derived type.

Assignment to a variable of a value type creates a `copy` of the value being assigned. This differs from assignment to a variable of a reference type, which copies the reference but not the object identified by the reference.

11.1.1 The System.ValueType type

All value types implicitly inherit from the class `System.ValueType`, which, in turn, inherits from class `Object`.

Note that `System.ValueType` is not itself a `value-type`. Rather, it is a `class-type` from which all `value-types` are automatically derived.

11.1.2 Default constructors

All value types implicitly declare a public parameterless instance constructor called the `default constructor`. The default constructor returns a zero-initialized instance known as the `default value` for the value type:

- For all `simple-types`, the default value is the value produced by a bit pattern of all zeros:
  - For `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, and `ulong`, the default value is 0.
  - For `char`, the default value is '\x0000'.
  - For `float`, the default value is 0.0f.
  - For `double`, the default value is 0.0d.
  - For `decimal`, the default value is 0m.
  - For `bool`, the default value is `false`.
- For an `enum-type E`, the default value is 0.
• For a struct-type, the default value is the value produced by setting all value type fields to their default value and all reference type fields to null.

Like any other instance constructor, the default constructor of a value type is invoked using the `new` operator. [Note: For efficiency reasons, this requirement is not intended to actually have the implementation generate a constructor call. For value types, the default value expression (§14.5.14) produces the same result as using the default constructor. end note] [Example: In the code below, variables `i`, `j` and `k` are all initialized to zero.]

```csharp
class A
{
    void F() {
        int i = 0;
        int j = new int();
        int k = default(int);
    }
}
```

end example]

Because every value type implicitly has a public parameterless instance constructor, it is not possible for a struct type to contain an explicit declaration of a parameterless constructor. A struct type is however permitted to declare parameterized instance constructors (§18.3.8).

### 11.1.3 Struct types

A struct type is a value type that can declare constants, fields, methods, properties, indexers, operators, instance constructors, static constructors, and nested types. Struct types are described in §18.

### 11.1.4 Simple types

C# provides a set of predefined struct types called the simple types. The simple types are identified through reserved words, but these reserved words are simply aliases for predefined struct types in the `System` namespace, as described in the table below.

<table>
<thead>
<tr>
<th>Reserved word</th>
<th>Aliased type</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sbyte</td>
<td>System.SByte</td>
</tr>
<tr>
<td>Byte</td>
<td>System.Byte</td>
</tr>
<tr>
<td>Short</td>
<td>System.Int16</td>
</tr>
<tr>
<td>Ushort</td>
<td>System.UInt16</td>
</tr>
<tr>
<td>Int</td>
<td>System.Int32</td>
</tr>
<tr>
<td>Uint</td>
<td>System.UInt32</td>
</tr>
<tr>
<td>Long</td>
<td>System.Int64</td>
</tr>
<tr>
<td>Ulong</td>
<td>System.UInt64</td>
</tr>
<tr>
<td>Char</td>
<td>System.Char</td>
</tr>
<tr>
<td>Float</td>
<td>System.Single</td>
</tr>
<tr>
<td>Double</td>
<td>System.Double</td>
</tr>
<tr>
<td>Bool</td>
<td>System.Boolean</td>
</tr>
<tr>
<td>Decimal</td>
<td>System.Decimal</td>
</tr>
</tbody>
</table>

Because a simple type aliases a struct type, every simple type has members. [Example: `int` has the members declared in `System.Int32` and the members inherited from `System.Object`, and the following statements are permitted:]
int i = int.MaxValue;    // System.Int32.MaxValue constant
string s = i.ToString(); // System.Int32.ToString() instance method
string t = 123.ToString(); // System.Int32.ToString() instance method

The simple types differ from other struct types in that they permit certain additional operations:

- Most simple types permit values to be created by writing literals (§9.4.4). [Example: 123 is a literal of type int and 'a' is a literal of type char. end example] C# makes no provision for literals of struct types in general.

- When the operands of an expression are all simple type constants, the compiler evaluates the expression at compile-time. Such an expression is known as a constant-expression (§14.16). Expressions involving operators defined by other struct types are not considered constant expressions.

- Through const declarations, it is possible to declare constants of the simple types (§17.3). It is not possible to have constants of other struct types, but a similar effect is provided by static readonly fields.

- Conversions involving simple types can participate in evaluation of conversion operators defined by other struct types, but a user-defined conversion operator can never participate in evaluation of another user-defined conversion operator (§13.4.2).

11.1.5 Integral types

C# supports nine integral types: sbyte, byte, short, ushort, int, uint, long, ulong, and char. The integral types have the following sizes and ranges of values:

- The sbyte type represents signed 8-bit integers with values from –128 to 127, inclusive.
- The byte type represents unsigned 8-bit integers with values from 0 to 255, inclusive.
- The short type represents signed 16-bit integers with values from –32768 to 32767, inclusive.
- The ushort type represents unsigned 16-bit integers with values from 0 to 65535, inclusive.
- The int type represents signed 32-bit integers with values from –2147483648 to 2147483647, inclusive.
- The uint type represents unsigned 32-bit integers with values from 0 to 4294967295, inclusive.
- The long type represents signed 64-bit integers with values from –9223372036854775808 to 9223372036854775807, inclusive.
- The ulong type represents unsigned 64-bit integers with values from 0 to 18446744073709551615, inclusive.

- The char type represents unsigned 16-bit integers with values from 0 to 65535, inclusive. The set of possible values for the char type corresponds to the Unicode character set. [Note: Although char has the same representation as ushort, not all operations permitted on one type are permitted on the other. end note]

The integral-type unary and binary operators always operate with signed 32-bit precision, unsigned 32-bit precision, signed 64-bit precision, or unsigned 64-bit precision, as detailed in clause §14.

The char type is classified as an integral type, but it differs from the other integral types in two ways:

- There are no implicit conversions from other types to the char type. In particular, even though the sbyte, byte, and ushort types have ranges of values that are fully representable using the char type, implicit conversions from sbyte, byte, or ushort to char do not exist.

- Constants of the char type shall be written as character-literals or as integer-literals in combination with a cast to type char. [Example: (char)10 is the same as '\x000A'. end example]
The checked and unchecked operators and statements are used to control overflow checking for integral-type arithmetic operations and conversions (§14.5.12). In a checked context, an overflow produces a compile-time error or causes a System.OverflowException to be thrown. In an unchecked context, overflows are ignored and any high-order bits that do not fit in the destination type are discarded.

11.1.6 Floating point types
C# supports two floating-point types: float and double. The float and double types are represented using the 32-bit single-precision and 64-bit double-precision IEC 60559 formats, which provide the following sets of values:

- Positive zero and negative zero. In most situations, positive zero and negative zero behave identically as the simple value zero, but certain operations distinguish between the two (§14.7.2).
- Positive infinity and negative infinity. Infinities are produced by such operations as dividing a non-zero number by zero. [Example: 1.0 / 0.0 yields positive infinity, and –1.0 / 0.0 yields negative infinity. end example]
- The Not-a-Number value, often abbreviated NaN. NaNs are produced by invalid floating-point operations, such as dividing zero by zero.
- The finite set of non-zero values of the form $s \times m \times 2^e$, where $s$ is 1 or –1, and $m$ and $e$ are determined by the particular floating-point type: For float, $0 < m < 2^{24}$ and $–149 \leq e \leq 104$, and for double, $0 < m < 2^{53}$ and $–1075 \leq e \leq 970$. Denormalized floating-point numbers are considered valid non-zero values. C# neither requires nor forbids that a conforming implementation support denormalized floating-point numbers.

The float type can represent values ranging from approximately $1.5 \times 10^{-45}$ to $3.4 \times 10^{38}$ with a precision of 7 digits.

The double type can represent values ranging from approximately $5.0 \times 10^{-324}$ to $1.7 \times 10^{308}$ with a precision of 15–16 digits.

The floating-point operators, including the assignment operators, never produce exceptions. Instead, in exceptional situations, floating-point operations produce zero, infinity, or NaN, as described below:

- The result of a floating-point operation is rounded to the nearest representable value in the destination format. This may cause a non-zero value to be rounded to zero.
- If the magnitude of the result of a floating-point operation is too large for the destination format, the result of the operation becomes positive infinity or negative infinity.
- If a floating-point operation is invalid, the result of the operation becomes NaN.
- If one or both operands of a floating-point operation is NaN, the result of the operation becomes NaN.

Floating-point operations can be performed with higher precision than the result type of the operation. [Example: Some hardware architectures support an "extended" or “long double” floating-point type with greater range and precision than the double type, and implicitly perform all floating-point operations using this higher precision type. Only at excessive cost in performance can such hardware architectures be made to perform floating-point operations with less precision, and rather than require an implementation to forfeit both performance and precision, C# allows a higher precision type to be used for all floating-point operations. Other than delivering more precise results, this rarely has any measurable effects. However, in expressions of the form $x \times y / z$, where the multiplication produces a result that is outside the double range, but the subsequent division brings the temporary result back into the double range, the fact that the expression is evaluated in a higher range format can cause a finite result to be produced instead of an infinity. end example]

11.1.7 The decimal type
The decimal type is a 128-bit data type suitable for financial and monetary calculations. The decimal type can represent values including those in the range $1 \times 10^{-28}$ through $1 \times 10^{28}$ with at least 28 significant digits.
The finite set of values of type `decimal` are of the form \((-1)^s \times c \times 10^e\), where the sign \(s\) is 0 or 1, the coefficient \(c\) is given by \(0 \leq c \leq C_{\text{max}}\), and the scale \(e\) is such that \(E_{\text{min}} \leq e \leq E_{\text{max}}\), where \(C_{\text{max}}\) is at least \(1 \times 10^{28}\), \(E_{\text{min}} \leq 0\), and \(E_{\text{max}} \geq 28\). The `decimal` type does not necessarily support signed zeros, infinities, or NaNs.

A `decimal` is represented as an integer scaled by a power of ten. For `decimals` with an absolute value less than \(1.0m\), the value is exact to at least the 28th decimal place. For `decimals` with an absolute value greater than or equal to \(1.0m\), the value is exact to at least 28 digits. Contrary to the `float` and `double` data types, `decimal` fractional numbers such as \(0.1\) can be represented exactly in the `decimal` representation. In the `float` and `double` representations, such numbers often have non-terminating binary expansions, making those representations more prone to round-off errors.

The result of an operation on values of type `decimal` is that which would result from calculating an exact result (preserving scale, as defined for each operator) and then rounding to fit the representation. Results are rounded to the nearest representable value, and, when a result is equally close to two representable values, to the value that has an even number in the least significant digit position (this is known as “banker’s rounding”). That is, results are exact to at least the 28th decimal place. Note that rounding may produce a zero value from a non-zero value.

If a `decimal` arithmetic operation produces a result whose magnitude is too large for the `decimal` format, a `System.OverflowException` is thrown.

The `decimal` type has greater precision but may have a smaller range than the floating-point types. Thus, conversions from the floating-point types to `decimal` might produce overflow exceptions, and conversions from `decimal` to the floating-point types might cause loss of precision or overflow exceptions. For these reasons, no implicit conversions exist between the floating-point types and `decimal`, and without explicit casts, a compile-time error occurs when floating-point and `decimal` operands are directly mixed in the same expression.

### 11.8 The bool type

The `bool` type represents Boolean logical quantities. The possible values of type `bool` are `true` and `false`.

No standard conversions exist between `bool` and other types. In particular, the `bool` type is distinct and separate from the integral types, and a `bool` value cannot be used in place of an integral value, and vice versa.

[Note: In the C and C++ languages, a zero integral or floating-point value, or a null pointer can be converted to the Boolean value `false`, and a non-zero integral or floating-point value, or a non-null pointer can be converted to the Boolean value `true`. In C#, such conversions are accomplished by explicitly comparing an integral or floating-point value to zero, or by explicitly comparing an object reference to `null`. end note]

### 11.9 Enumeration types

An enumeration type is a distinct type with named constants. Every enumeration type has an underlying type, which shall be `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `long` or `ulong`. Enumeration types are defined through enumeration declarations (§21.1). The direct base type of every enumeration type is the class `System.Enum`. The direct base class of `System.Enum` is `System.ValueType`.

### 11.2 Reference types

A reference type is a class type, an interface type, an array type, or a delegate type.
11.2.1 Class types
A class type defines a data structure that contains data members (constants and fields), function members (methods, properties, events, indexers, operators, instance constructors, finalizers, and static constructors), and nested types. Class types support inheritance, a mechanism whereby derived classes can extend and specialize base classes. Instances of class types are created using object-creation-expressions (§14.5.10.1). Class types are described in §17.

11.2.2 The object type
The object class type is the ultimate base class of all other types. Every type in C# directly or indirectly derives from the object class type.

The keyword object is simply an alias for the predefined class System.Object.

11.2.3 The string type
The string type is a sealed class type that inherits directly from object. Instances of the string class represent Unicode character strings.

Values of the string type can be written as string literals (§9.4.4).

The keyword string is simply an alias for the predefined class System.String.

11.2.4 Interface types
An interface defines a contract. A class or struct that implements an interface shall adhere to its contract. An interface can inherit from multiple base interfaces, and a class or struct can implement multiple interfaces.
Interface types are described in §20.

11.2.5 Array types
An array is a data structure that contains zero or more variables which are accessed through computed indices. The variables contained in an array, also called the elements of the array, are all of the same type, and this type is called the element type of the array.

Array types are described in §19.

11.2.6 Delegate types
A delegate is a data structure that refers to one or more methods, and for instance methods, it also refers to their corresponding object instances.

[Note: The closest equivalent of a delegate in C or C++ is a function pointer, but whereas a function pointer can only reference static functions, a delegate can reference both static and instance methods. In the latter case, the delegate stores not only a reference to the method’s entry point, but also a reference to the object instance on which to invoke the method. end note]

Delegate types are described in §22.

11.2.7 The null type
The null literal (§9.4.4.6) evaluates to the null value, which is used to denote a reference not pointing at any object or array, or the absence of a value. The null type has a single value, which is the null value. Hence an expression whose type is the null type can evaluate only to the null value. There is no way to explicitly write the null type and, therefore, no way to use it in a declared type.

Moreover, the null type can never be the type inferred for a type parameter (§25.6.4).

11.3 Boxing and unboxing
The concept of boxing and unboxing is central to C#’s type system. It provides a bridge between value-types and reference-types by permitting any value of a value-type to be converted to and from type object.

Boxing and unboxing enables a unified view of the type system wherein a value of any type can ultimately be treated as an object.

11.3.1 Boxing conversions
A boxing conversion permits any value-type to be implicitly converted to object or System.ValueType or to any interface-type implemented by the value-type. Furthermore, there is an implicit boxing conversion from any enumeration type to System.Enum. Boxing a value of a value-type consists of allocating an object instance and copying the value-type value into that instance.

The actual process of boxing a value of a value-type is best explained by imagining the existence of a boxing class for that type. [Example: For any value-type T, the boxing class behaves as if it were declared as follows:

```csharp
sealed class T_Box
{
    T value;
    public T_Box(T t) {
        value = t;
    }
}
```

Boxing of a value v of type T now consists of executing the expression new T_Box(v), and returning the resulting instance as a value of type object. Thus, the statements

```csharp
int i = 123;
object box = i;
```

conceptually correspond to
int i = 123;
object box = new int_Box(i);

end example]

Boxing classes like T_Box and int_Box above don't actually exist and the dynamic type of a boxed value isn't actually a class type. Instead, a boxed value of type T has the dynamic type T, and a dynamic type check using the is operator can simply reference type T. [Example:
int i = 123;
object box = i;
if (box is int) {
    Console.Write("Box contains an int");
}

will output the string “Box contains an int” on the console. end example]

A boxing conversion implies making a copy of the value being boxed. This is different from a conversion of a reference-type to type object, in which the value continues to reference the same instance and simply is regarded as the less derived type object. [Example: Given the declaration

```csharp
struct Point
{
    public int x, y;
    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
```

the following statements
Point p = new Point(10, 10);
object box = p;
p.x = 20;
Console.Write(((Point)box).x);

will output the value 10 on the console because the implicit boxing operation that occurs in the assignment of p to box causes the value of p to be copied. Had Point been declared a class instead, the value 20 would be output because p and box would reference the same instance. end example]

11.3.2 Unboxing conversions

An unboxing conversion permits an explicit conversion from object or System.ValueType to any value-type or from any interface-type to any value-type that implements the interface-type. Furthermore, there is an explicit unboxing conversion from System.Enum to any enumeration type. An unboxing operation consists of first checking that the object instance is a boxed value of the given value-type, and then copying the value out of the instance.

Referring to the imaginary boxing class described in the previous subclause, an unboxing conversion of an object box to a value-type T consists of executing the expression ((T_Box)box).value. [Example: Thus, the statements

```csharp
object box = 123;
int i = (int)box;
```

conceptually correspond to

```csharp
object box = new int_Box(123);
int i = ((int_Box)box).value;
```

end example]

For an unboxing conversion to a given value-type to succeed at run-time, the value of the source operand shall be a reference to an object that was previously created by boxing a value of that value-type. If the source operand is null a System.NullReferenceException is thrown. If the source operand is a reference to an incompatible object, a System.InvalidCastException is thrown.

11 Types
11.4 Nullable types

A nullable type is classified as a value type (§11.1).

The type specified before the ? modifier in a nullable type is called the underlying type of the nullable type. The underlying type of a nullable type shall be any non-nullable value type or any type parameter that is constrained (§25.7) to non-nullable value types (that is, any type parameter with a struct constraint). The underlying type of a nullable type shall not be a nullable type or a reference type. [Example: int?? and string? are invalid types. end example] A nullable type can represent all values of its underlying type plus an additional null value. T? and System.Nullable<T> denote the same type.

11.4.1 Members

An instance of a nullable type T? has two public read-only properties:

- A HasValue property of type bool
- A Value property of type T

An instance for which HasValue is true is said to be non-null. A non-null instance contains a known value and Value returns that value.

An instance for which HasValue is false is said to be null. Attempting to read the Value of a null instance causes a System.InvalidOperationException to be thrown.

In addition to the default constructor, every nullable type T? has a public constructor that takes a single argument of type T. Given a value x of type T, a constructor invocation of the form

```
new T?(x)
```

creates a non-null instance of T? for which the Value property is x.

It is never necessary to explicitly invoke a nullable type’s constructor, since equivalent functionality is provided as an implicit conversion from T to T?.

11.4.2 Implemented interfaces

A type of the form T? implements the same interfaces (§20) as System.Nullable<T>. This typically means that the sets of interfaces implemented by T and T? are different.
12. Variables

Variables represent storage locations. Every variable has a type that determines what values can be stored in the variable. C# is a type-safe language, and the C# compiler guarantees that values stored in variables are always of the appropriate type. The value of a variable can be changed through assignment or through use of the ++ and -- operators.

A variable shall be **definitely assigned** (§12.3) before its value can be obtained.

As described in the following subclauses, variables are either **initially assigned** or **initially unassigned**. An initially assigned variable has a well-defined initial value and is always considered definitely assigned. An initially unassigned variable has no initial value. For an initially unassigned variable to be considered definitely assigned at a certain location, an assignment to the variable shall occur in every possible execution path leading to that location.

### 12.1 Variable categories

C# defines seven categories of variables: static variables, instance variables, array elements, value parameters, reference parameters, output parameters, and local variables. The subclauses that follow describe each of these categories.

**Example:** In the following code

```csharp
class A
{
    public static int x;
    int y;
    void F(int[] v, int a, ref int b, out int c) {
        int i = 1;
        c = a + b++;
    }
}
```

x is a static variable, y is an instance variable, v[0] is an array element, a is a value parameter, b is a reference parameter, c is an output parameter, and i is a local variable. *end example*

#### 12.1.1 Static variables

A field declared with the `static` modifier is called a **static variable**. A static variable comes into existence before execution of the static constructor (§17.11) for its containing type, and ceases to exist when the associated application domain ceases to exist.

The initial value of a static variable is the default value (§12.2) of the variable’s type.

For the purposes of definite assignment checking, a static variable is considered initially assigned.

#### 12.1.2 Instance variables

A field declared without the `static` modifier is called an **instance variable**.

12.1.2.1 Instance variables in classes

An instance variable of a class comes into existence when a new instance of that class is created, and ceases to exist when there are no references to that instance and the instance’s finalizer (if any) has executed.

The initial value of an instance variable of a class is the default value (§12.2) of the variable’s type.

For the purpose of definite assignment checking, an instance variable is considered initially assigned.
12.1.2.2 Instance variables in structs
An instance variable of a struct has exactly the same lifetime as the struct variable to which it belongs. In
other words, when a variable of a struct type comes into existence or ceases to exist, so too do the instance
variables of the struct.

The initial assignment state of an instance variable of a struct is the same as that of the containing struct
variable. In other words, when a struct variable is considered initially assigned, so too are its instance
variables, and when a struct variable is considered initially unassigned, its instance variables are likewise
unassigned.

12.1.3 Array elements
The elements of an array come into existence when an array instance is created, and cease to exist when
there are no references to that array instance.

The initial value of each of the elements of an array is the default value (§12.2) of the type of the array
elements.

For the purpose of definite assignment checking, an array element is considered initially assigned.

12.1.4 Value parameters
A parameter declared without a ref or out modifier is a value parameter.

A value parameter comes into existence upon invocation of the function member (method, instance
constructor, accessor, or operator) to which the parameter belongs, and is initialized with the value of the
argument given in the invocation. A value parameter ceases to exist upon return of the function member
(except when the value parameter is captured by an anonymous method (§14.5.15.3.1) or the function
member body is an iterator block (§26)).

For the purpose of definite assignment checking, a value parameter is considered initially assigned.

12.1.5 Reference parameters
A parameter declared with a ref modifier is a reference parameter.

A reference parameter does not create a new storage location. Instead, a reference parameter represents the
same storage location as the variable given as the argument in the function member invocation. Thus, the
value of a reference parameter is always the same as the underlying variable.

The following definite assignment rules apply to reference parameters. [Note: The rules for output
parameters are different, and are described in §12.1.6. end note]

- A variable shall be definitely assigned (§12.3) before it can be passed as a reference parameter in a
  function member invocation.

- Within a function member, a reference parameter is considered initially assigned.

Within an instance method or instance accessor of a struct type, the this keyword behaves exactly as a
reference parameter of the struct type (§14.5.7).

12.1.6 Output parameters
A parameter declared with an out modifier is an output parameter.

An output parameter does not create a new storage location. Instead, an output parameter represents the
same storage location as the variable given as the argument in the function member invocation. Thus, the
value of an output parameter is always the same as the underlying variable.

The following definite assignment rules apply to output parameters. [Note: The rules for reference
parameters are different, and are described in §12.1.5. end note]
- A variable need not be definitely assigned before it can be passed as an output parameter in a function member invocation.

- Following the normal completion of a function member invocation, each variable that was passed as an output parameter is considered assigned in that execution path.

- Within a function member, an output parameter is considered initially unassigned.

- Every output parameter of a function member shall be definitely assigned (§12.3) before the function member returns normally.

Within an instance constructor of a struct type, the `this` keyword behaves exactly as an output or reference parameter of the struct type, depending on whether the constructor declaration includes a constructor initializer (§14.5.7).

### 12.1.7 Local variables

A **local variable** is declared by a `local-variable-declaration`, `foreach-statement`, or `specific-catch-clause` of a `try-statement`. For a `foreach-statement`, the local variable is an iteration variable (§15.8.4). For a `specific-catch-clause`, the local variable is an exception variable (§15.10). A local variable declared by a `foreach-statement` or `specific-catch-clause` is considered initially assigned.

A `local-variable-declaration` can occur in a `block`, a `for-statement`, a `switch-block`, or a `using-statement`.

The lifetime of a local variable is the portion of program execution during which storage is guaranteed to be reserved for it. This lifetime extends from entry into the scope with which it is associated, at least until execution of that scope ends in some way. (Entering an enclosed `block`, calling a method, or yielding a value from an iterator block suspends, but does not end, execution of the current scope.) If the local variable is captured by an anonymous method, the lifetime of the variable is extended at least until all referencing delegates are eligible for garbage collection (§14.5.15.3.1). If the parent scope is entered recursively or iteratively, a new instance of the local variable is created each time, and its `local-variable-initializer`, if any, is evaluated each time. [Note: A local variable is instantiated each time its scope is entered. This behavior is visible to user code containing anonymous methods. end note]

A local variable introduced by a `local-variable-declaration` is not automatically initialized and thus has no default value. Such a local variable is considered initially unassigned. A `local-variable-declaration` can include a `local-variable-initializer`, in which case the variable is considered definitely assigned in its entire scope, except within the expression provided in the `local-variable-initializer`.

Within the scope of a local variable, it is a compile-time error to refer to that local variable in a textual position that precedes its `local-variable-declarator`.

[Note: The actual lifetime of a local variable is implementation-dependent. For example, a compiler might statically determine that a local variable in a block is only used for a small portion of that block. Using this analysis, the compiler could generate code that results in the variable’s storage having a shorter lifetime than its containing block.

The storage referred to by a local reference variable is reclaimed independently of the lifetime of that local reference variable (§10.9). end note]

### 12.2 Default values

The following categories of variables are automatically initialized to their default values:

- Static variables
- Instance variables of class instances
- Array elements

The default value of a variable depends on the type of the variable and is determined as follows:
• For a variable of a value-type, the default value is the same as the value computed by the value-type’s default constructor (§11.1.2).

• For a variable of a reference-type, the default value is null.

[Note: Initialization to default values is typically done by having the memory manager or garbage collector initialize memory to all-bits-zero before it is allocated for use. For this reason, it is convenient to use all-bits-zero to represent the null reference. end note]

The default value of a nullable type is an instance for which the HasValue property is false. Referencing the Value property of a default value of a nullable type results in an exception of type System.InvalidOperationException. The default value is also known as the null value of the nullable type. An implicit conversion exists from the null type (§11.2.7) to any nullable type, and this conversion produces the null value of the type.

### 12.3 Definite assignment

At a given location in the executable code of a function member, a variable is said to be definitely assigned if the compiler can prove, by a particular static flow analysis (§12.3.3), that the variable has been automatically initialized or has been the target of at least one assignment. [Note: Informally stated, the rules of definite assignment are:

• An initially assigned variable (§12.3.1) is always considered definitely assigned.

• An initially unassigned variable (§12.3.2) is considered definitely assigned at a given location if all possible execution paths leading to that location contain at least one of the following:
  o A simple assignment (§14.14.1) in which the variable is the left operand.
  o An invocation expression (§14.5.5) or object creation expression (§14.5.10.1) that passes the variable as an output parameter.
  o For a local variable, a local variable declaration (§15.5) that includes a variable initializer.

The formal specification underlying the above informal rules is described in §12.3.1, §12.3.2, and §12.3.3. end note]

The definite assignment states of instance variables of a struct-type variable are tracked individually as well as collectively. In addition to the rules above, the following rules apply to struct-type variables and their instance variables:

• An instance variable is considered definitely assigned if its containing struct-type variable is considered definitely assigned.

• A struct-type variable is considered definitely assigned if each of its instance variables is considered definitely assigned.

Definite assignment is a requirement in the following contexts:

• A variable shall be definitely assigned at each location where its value is obtained. [Note: This ensures that undefined values never occur. end note] The occurrence of a variable in an expression is considered to obtain the value of the variable, except when
  o the variable is the left operand of a simple assignment,
  o the variable is passed as an output parameter, or
  o the variable is a struct-type variable and occurs as the left operand of a member access.

• A variable shall be definitely assigned at each location where it is passed as a reference parameter. [Note: This ensures that the function member being invoked can consider the reference parameter initially assigned. end note]

• All output parameters of a function member shall be definitely assigned at each location where the function member returns (through a return statement or through execution reaching the end of the
function member body). [Note: This ensures that function members do not return undefined values in output parameters, thus enabling the compiler to consider a function member invocation that takes a variable as an output parameter equivalent to an assignment to the variable. end note]

- The `this` variable of a `struct-type` instance constructor shall be definitely assigned at each location where that instance constructor returns.

### 12.3.1 Initially assigned variables

The following categories of variables are classified as initially assigned:

- Static variables
- Instance variables of class instances
- Instance variables of initially assigned struct variables
- Array elements
- Value parameters
- Reference parameters
- Variables declared by a `catch` clause, a `foreach` statement, or a `using` statement.

### 12.3.2 Initially unassigned variables

The following categories of variables are classified as initially unassigned:

- Instance variables of initially unassigned struct variables.
- Output parameters, including the `this` variable of struct instance constructors without a constructor initializer.
- Local variables, except those declared in a `catch` clause, a `foreach` statement, or a `using` statement.

### 12.3.3 Precise rules for determining definite assignment

In order to determine that each used variable is definitely assigned, the compiler shall use a process that is equivalent to the one described in this subclause.

The compiler processes the body of each function member that has one or more initially unassigned variables. For each initially unassigned variable \( v \), the compiler determines a **definite assignment state** for \( v \) at each of the following points in the function member:

- At the beginning of each statement
- At the end point (§15.1) of each statement
- On each arc which transfers control to another statement or to the end point of a statement
- At the beginning of each expression
- At the end of each expression

The definite assignment state of \( v \) can be either:

- Definitely assigned. This indicates that on all possible control flows to this point, \( v \) has been assigned a value.
- Not definitely assigned. For the state of a variable at the end of an expression of type `bool`, the state of a variable that isn’t definitely assigned might (but doesn’t necessarily) fall into one of the following substates:
The following rules govern how the state of a variable \( v \) is determined at each location.

### 12.3.3.1 General rules for statements

- \( v \) is not definitely assigned at the beginning of a function member body.
- \( v \) is definitely assigned at the beginning of any unreachable statement.
- The definite assignment state of \( v \) at the beginning of any other statement is determined by checking the definite assignment state of \( v \) on all control flow transfers that target the beginning of that statement. If \( v \) is definitely assigned on all such control flow transfers, then \( v \) is definitely assigned at the beginning of the statement. The set of possible control flow transfers is determined in the same way as for checking statement reachability (§15.1).
- The definite assignment state of \( v \) at the end point of a block, checked, unchecked, if, while, do, for, foreach, lock, using, or switch statement is determined by checking the definite assignment state of \( v \) on all control flow transfers that target the end point of that statement. If \( v \) is definitely assigned on all such control flow transfers, then \( v \) is definitely assigned at the end point of the statement. Otherwise, \( v \) is not definitely assigned at the end point of the statement. The set of possible control flow transfers is determined in the same way as for checking statement reachability (§15.1).

### 12.3.3.2 Block statements, checked, and unchecked statements

The definite assignment state of \( v \) on the control transfer to the first statement of the statement list in the block (or to the end point of the block, if the statement list is empty) is the same as the definite assignment state of \( v \) before the block, checked, or unchecked statement.

### 12.3.3.3 Expression statements

For an expression statement \( stmt \) that consists of the expression \( expr \):

- \( v \) has the same definite assignment state at the beginning of \( expr \) as at the beginning of \( stmt \).
- If \( v \) is definitely assigned at the end of \( expr \), it is definitely assigned at the end point of \( stmt \); otherwise, it is not definitely assigned at the end point of \( stmt \).

### 12.3.3.4 Declaration statements

- If \( stmt \) is a declaration statement without initializers, then \( v \) has the same definite assignment state at the end point of \( stmt \) as at the beginning of \( stmt \).
- If \( stmt \) is a declaration statement with initializers, then the definite assignment state for \( v \) is determined as if \( stmt \) were a statement list, with one assignment statement for each declaration with an initializer (in the order of declaration).

### 12.3.3.5 If statements

For an if statement \( stmt \) of the form:

\[
\text{if } ( expr ) \text{ then-stmt else else-stmt}
\]

- \( v \) has the same definite assignment state at the beginning of \( expr \) as at the beginning of \( stmt \).
- If \( v \) is definitely assigned at the end of \( expr \), then it is definitely assigned on the control flow transfer to \( then-stmt \) and to either \( else-stmt \) or to the end-point of \( stmt \) if there is no else clause.
12.3.3.6 Switch statements
In a `switch` statement `stmt` with a controlling expression `expr`:

- The definite assignment state of `v` at the beginning of `expr` is the same as the state of `v` at the beginning of `stmt`.
- The definite assignment state of `v` on the control flow transfer to a reachable switch block statement list is the same as the definite assignment state of `v` at the end of `expr`.

12.3.3.7 While statements
For a `while` statement `stmt` of the form:

```c
while ( expr ) while-body
```

- `v` has the same definite assignment state at the beginning of `expr` as at the beginning of `stmt`.
- If `v` is definitely assigned at the end of `expr`, then it is definitely assigned on the control flow transfer to `while-body` and to the end point of `stmt`.
- If `v` has the state “definitely assigned after true expression” at the end of `expr`, then it is definitely assigned on the control flow transfer to `while-body`, but not definitely assigned at the end-point of `stmt`.
- If `v` has the state “definitely assigned after false expression” at the end of `expr`, then it is definitely assigned on the control flow transfer to the end point of `stmt`, but not definitely assigned on the control flow transfer to `while-body`.

12.3.3.8 Do statements
For a `do` statement `stmt` of the form:

```c
do do-body while ( expr ) ;
```

- `v` has the same definite assignment state on the control flow transfer from the beginning of `stmt` to `do-body` as at the beginning of `stmt`.
- `v` has the same definite assignment state at the beginning of `expr` as at the end point of `do-body`.
- If `v` is definitely assigned at the end of `expr`, then it is definitely assigned on the control flow transfer to the end point of `stmt`.
- If `v` has the state “definitely assigned after false expression” at the end of `expr`, then it is definitely assigned on the control flow transfer to the end point of `stmt`, but not definitely assigned on the control flow transfer to `do-body`.

12.3.3.9 For statements
Definite assignment checking for a `for` statement of the form:

```c
for ( for-initializer ; for-condition ; for-iterator ) embedded-statement
```
is done as if the statement were written:
{ 
    for-initializer;
    while (for-condition) {
        embedded-statement;
        LLoop:
        for-iterator;
    }
}

with continue statements that target the for statement being translated to goto statements targeting the 
label LLoop. If the for-condition is omitted from the for statement, then evaluation of definite assignment 
proceeds as if for-condition were replaced with true in the above expansion.

12.3.3.10 Break, continue, and goto statements
The definite assignment state of v on the control flow transfer caused by a break, continue, or goto 
statement is the same as the definite assignment state of v at the beginning of the statement.

12.3.3.11 Throw statements
For a statement stmt of the form

    throw expr;

the definite assignment state of v at the beginning of expr is the same as the definite assignment state of v at 
the beginning of stmt.

12.3.3.12 Return statements
For a statement stmt of the form

    return expr;

- The definite assignment state of v at the beginning of expr is the same as the definite assignment state of 
v at the beginning of stmt.
- If v is an output parameter, then it shall be definitely assigned either:
  o after expr
  o or at the end of the finally block of a try-finally or try-catch-finally that encloses the 
    return statement.

For a statement stmt of the form:

    return;

- If v is an output parameter, then it shall be definitely assigned either:
  o before stmt
  o or at the end of the finally block of a try-finally or try-catch-finally that encloses the 
    return statement.

12.3.3.13 Try-catch statements
For a statement stmt of the form:

    try try-block
    catch ( ... ) catch-block-1
    ...
    catch ( ... ) catch-block-n

- The definite assignment state of v at the beginning of try-block is the same as the definite assignment 
state of v at the beginning of stmt.
• The definite assignment state of \( v \) at the beginning of catch-block-\( i \) (for any \( i \)) is the same as the definite assignment state of \( v \) at the beginning of \( stmt \).

• The definite assignment state of \( v \) at the end-point of \( stmt \) is definitely assigned if (and only if) \( v \) is definitely assigned at the end-point of try-block and every catch-block-\( i \) (for every \( i \) from 1 to \( n \)).

12.3.3.14 Try-finally statements

For a try statement \( stmt \) of the form:

\[
\text{try try-block finally finally-block}
\]

• The definite assignment state of \( v \) at the beginning of try-block is the same as the definite assignment state of \( v \) at the beginning of \( stmt \).

• The definite assignment state of \( v \) at the beginning of finally-block is the same as the definite assignment state of \( v \) at the beginning of \( stmt \).

• The definite assignment state of \( v \) at the end-point of \( stmt \) is definitely assigned if (and only if) either:
  - \( v \) is definitely assigned at the end-point of try-block
  - \( v \) is definitely assigned at the end-point of finally-block

If a control flow transfer (such as a goto statement) is made that begins within try-block, and ends outside of try-block, then \( v \) is also considered definitely assigned on that control flow transfer if \( v \) is definitely assigned at the end-point of finally-block. (This is not an only if—if \( v \) is definitely assigned for another reason on this control flow transfer, then it is still considered definitely assigned.)

12.3.3.15 Try-catch-finally statements

Definite assignment analysis for a try-catch-finally statement of the form:

\[
\text{try try-block} \\
\text{catch ( ... ) catch-block-1} \\
... \\
\text{catch ( ... ) catch-block-\( n \)} \\
\text{finally finally-block}
\]

is done as if the statement were a try-finally statement enclosing a try-catch statement:

\[
\text{try} \\
\text{try try-block} \\
\text{catch ( ... ) catch-block-1} \\
... \\
\text{catch ( ... ) catch-block-\( n \)} \\
\text{finally finally-block}
\]

[Example: The following example demonstrates how the different blocks of a try statement (§15.10) affect definite assignment.

```java
class A {
    static void F() {
        int i, j;
        try {
            goto LABEL;
            // neither i nor j definitely assigned
            i = 1;
            // i definitely assigned
        }
    }
```
catch {
    // neither i nor j definitely assigned
    i = 3;
    // i definitely assigned
}
finally {
    // neither i nor j definitely assigned
    j = 5;
    // j definitely assigned
} // i and j definitely assigned
LABEL:;
// j definitely assigned

12.3.3.16 Foreach statements
For a foreach statement stmt of the form:
   foreach (type identifier in expr) embedded-statement
- The definite assignment state of v at the beginning of expr is the same as the state of v at the beginning of stmt.
- The definite assignment state of v on the control flow transfer to embedded-statement or to the end point of stmt is the same as the state of v at the end of expr.

12.3.3.17 Using statements
For a using statement stmt of the form:
   using (resource-acquisition) embedded-statement
- The definite assignment state of v at the beginning of resource-acquisition is the same as the state of v at the beginning of stmt.
- The definite assignment state of v on the control flow transfer to embedded-statement is the same as the state of v at the end of resource-acquisition.

12.3.3.18 Lock statements
For a lock statement stmt of the form:
   lock (expr) embedded-statement
- The definite assignment state of v at the beginning of expr is the same as the state of v at the beginning of stmt.
- The definite assignment state of v on the control flow transfer to embedded-statement is the same as the state of v at the end of expr.

12.3.3.19 General rules for simple expressions
The following rule applies to these kinds of expressions: literals (§14.5.1), simple names (§14.5.2), member access expressions (§14.5.4), non-indexed base access expressions (§14.5.8), and typeof expressions (§14.5.11).
- The definite assignment state of v at the end of such an expression is the same as the definite assignment state of v at the beginning of the expression.
12.3.3.20 General rules for expressions with embedded expressions

The following rules apply to these kinds of expressions: parenthesized expressions (§14.5.3), element access expressions (§14.5.6), base access expressions with indexing (§14.5.8), increment and decrement expressions (§14.5.9, §14.6.5), cast expressions (§14.6.6), unary \(\pm, -, \sim, \oplus\) expressions, binary \(+, -, \times, \div, \mod\), \(<, >, <<=, >=>, ==, !=, i++, i--, as, &\), \&\& expressions (§14.7, §14.8, §14.9, §14.10), compound assignment expressions (§14.14.2), checked and unchecked expressions (§14.5.12), array and delegate creation expressions (§14.5.10).

Each of these expressions has one or more sub-expressions that are unconditionally evaluated in a fixed order. [Example: The binary \% operator evaluates the left hand side of the operator, then the right hand side. An indexing operation evaluates the indexed expression, and then evaluates each of the index expressions, in order from left to right. end example] For an expression \(expr\), which has sub-expressions \(expr_1, expr_2, ..., expr_n\), evaluated in that order:

- The definite assignment state of \(v\) at the beginning of \(expr_i\) is the same as the definite assignment state at the beginning of \(expr\).
- The definite assignment state of \(v\) at the beginning of \(expr_i\) \((i\) greater than one\) is the same as the definite assignment state at the end of \(expr_{i-1}\).
- The definite assignment state of \(v\) at the end of \(expr\) is the same as the definite assignment state at the end of \(expr_n\).

12.3.3.21 Invocation expressions and object creation expressions

For an invocation expression \(expr\) of the form:

\[
\text{primary-expression} ( \ arg_1, \ arg_2, \ ... \ arg_n )
\]

or an object creation expression \(expr\) of the form:

\[
\text{new type} ( \ arg_1, \ arg_2, \ ... \ arg_n )
\]

- For an invocation expression, the definite assignment state of \(v\) before \(primary-expression\) is the same as the state of \(v\) before \(expr\).
- For an invocation expression, the definite assignment state of \(v\) before \(arg_i\) is the same as the state of \(v\) after \(primary-expression\).
- For an object creation expression, the definite assignment state of \(v\) before \(arg_i\) is the same as the state of \(v\) before \(expr\).
- For each argument \(arg_i\), the definite assignment state of \(v\) after \(arg_i\) is determined by the normal expression rules, ignoring any \textit{ref} or \textit{out} modifiers.
- For each argument \(arg_i\) for any \(i\) greater than one, the definite assignment state of \(v\) before \(arg_i\) is the same as the state of \(v\) after \(arg_{i-1}\).
- If the variable \(v\) is passed as an \textit{out} argument (i.e., an argument of the form \textit{“out} \(v\)”) in any of the arguments, then the state of \(v\) after \(expr\) is definitely assigned. Otherwise, the state of \(v\) after \(expr\) is the same as the state of \(v\) after \(arg_n\).

12.3.3.22 Simple assignment expressions

For an expression \(expr\) of the form \(w = expr-rhs\):

- The definite assignment state of \(v\) before \(w\) is the same as the definite assignment state of \(v\) before \(expr\).
- The definite assignment state of \(v\) before \(expr-rhs\) is the same as the definite assignment state of \(v\) after \(w\).
• If \( w \) is the same variable as \( v \), then the definite assignment state of \( v \) after \( expr \) is definitely assigned. Otherwise, the definite assignment state of \( v \) after \( expr \) is the same as the definite assignment state of \( v \) after \( expr-rhs \).

[Example: In the following code

```csharp
class A
{
    static void F(int[] arr) {
        int x;
        arr[x = 1] = x;  // ok
    }
}
```

the variable \( x \) is considered definitely assigned after \( arr[x = 1] \) is evaluated as the left hand side of the second simple assignment. end example]

12.3.3.23 && expressions

For an expression \( expr \) of the form \( expr-first \&\& expr-second \):

• The definite assignment state of \( v \) before \( expr-first \) is the same as the definite assignment state of \( v \) before \( expr \).

• The definite assignment state of \( v \) before \( expr-second \) is definitely assigned if the state of \( v \) after \( expr-first \) is either definitely assigned or “definitely assigned after true expression”. Otherwise, it is not definitely assigned.

• The definite assignment state of \( v \) after \( expr \) is determined by:
  - If the state of \( v \) after \( expr-first \) is definitely assigned, then the state of \( v \) after \( expr \) is definitely assigned.
  - Otherwise, if the state of \( v \) after \( expr-second \) is definitely assigned, and the state of \( v \) after \( expr-first \) is “definitely assigned after false expression”, then the state of \( v \) after \( expr \) is definitely assigned.
  - Otherwise, if the state of \( v \) after \( expr-second \) is definitely assigned or “definitely assigned after true expression”, then the state of \( v \) after \( expr \) is “definitely assigned after false expression”.
  - Otherwise, if the state of \( v \) after \( expr-first \) is “definitely assigned after false expression”, and the state of \( v \) after \( expr-second \) is “definitely assigned after false expression”, then the state of \( v \) after \( expr \) is “definitely assigned after false expression”.
  - Otherwise, the state of \( v \) after \( expr \) is not definitely assigned.

[Example: In the following code

```csharp
class A
{
    static void F(int x, int y) {
        int i;
        if (x >= 0 && (i = y) >= 0) {
            // i definitely assigned
        }
        else {
            // i not definitely assigned
        }
    }
}
```

the variable \( i \) is considered definitely assigned in one of the embedded statements of an if statement but not in the other. In the if statement in method \( F \), the variable \( i \) is definitely assigned in the first embedded statement because execution of the expression \( (i = y) \) always precedes execution of this embedded statement. In contrast, the variable \( i \) is not definitely assigned in the second embedded statement, since \( x >= 0 \) might have tested false, resulting in the variable \( i \)’s being unassigned. end example]
12.3.3.24 \textbf{|| expressions}

For an expression \textit{expr} of the form \textit{expr-first} \textbf{||} \textit{expr-second}:

- The definite assignment state of \textit{v} before \textit{expr-first} is the same as the definite assignment state of \textit{v} before \textit{expr}.
- The definite assignment state of \textit{v} before \textit{expr-second} is definitely assigned if the state of \textit{v} after \textit{expr-first} is either definitely assigned or “definitely assigned after false expression”. Otherwise, it is not definitely assigned.
- The definite assignment statement of \textit{v} after \textit{expr} is determined by:
  - If the state of \textit{v} after \textit{expr-first} is definitely assigned, then the state of \textit{v} after \textit{expr} is definitely assigned.
  - Otherwise, if the state of \textit{v} after \textit{expr-second} is definitely assigned or “definitely assigned after false expression”, then the state of \textit{v} after \textit{expr} is “definitely assigned after true expression”.
  - Otherwise, if the state of \textit{v} after \textit{expr-first} is “definitely assigned after true expression”, and the state of \textit{v} after \textit{expr-second} is “definitely assigned after true expression”, then the state of \textit{v} after \textit{expr} is “definitely assigned after true expression”.
  - Otherwise, the state of \textit{v} after \textit{expr} is not definitely assigned.

[Example: In the following code

```java
class A {
    static void G(int x, int y) {
        int i;
        if (x >= 0 || (i = y) >= 0) {
            // i not definitely assigned
        } else {
            // i definitely assigned
        }
        // i not definitely assigned
    }
}
```

the variable \textit{i} is considered definitely assigned in one of the embedded statements of an \textit{if} statement but not in the other. In the \textit{if} statement in method \textit{G}, the variable \textit{i} is definitely assigned in the second embedded statement because execution of the expression \((i = y)\) always precedes execution of this embedded statement. In contrast, the variable \textit{i} is not definitely assigned in the first embedded statement, since \textit{x >= 0} might have tested true, resulting in the variable \textit{y}'s being unassigned. end example]

12.3.3.25 \textbf{! expressions}

For an expression \textit{expr} of the form \textit{! expr-operand}:

- The definite assignment state of \textit{v} before \textit{expr-operand} is the same as the definite assignment state of \textit{v} before \textit{expr}.
- The definite assignment state of \textit{v} after \textit{expr} is determined by:
  - If the state of \textit{v} after \textit{expr-operand} is definitely assigned, then the state of \textit{v} after \textit{expr} is definitely assigned.
  - Otherwise, if the state of \textit{v} after \textit{expr-operand} is not definitely assigned, then the state of \textit{v} after \textit{expr} is not definitely assigned.
  - Otherwise, if the state of \textit{v} after \textit{expr-operand} is “definitely assigned after false expression”, then the state of \textit{v} after \textit{expr} is “definitely assigned after true expression”.

129
12.3.3.26 ?: expressions

For an expression `expr` of the form `expr-cond ? expr-true : expr-false`:

- The definite assignment state of `v` before `expr-cond` is the same as the state of `v` before `expr`.
- The definite assignment state of `v` before `expr-true` is definitely assigned if and only if the state of `v` after `expr-cond` is definitely assigned or “definitely assigned after true expression”.
- The definite assignment state of `v` before `expr-false` is definitely assigned if and only if the state of `v` after `expr-cond` is definitely assigned or “definitely assigned after false expression”.
- The definite assignment state of `v` after `expr` is determined by:
  - If `expr-cond` is a constant expression (§14.16) with value `true` then the state of `v` after `expr` is the same as the state of `v` after `expr-true`.
  - Otherwise, if `expr-cond` is a constant expression (§14.16) with value `false` then the state of `v` after `expr` is the same as the state of `v` after `expr-false`.
  - Otherwise, if the state of `v` after `expr-true` is definitely assigned and the state of `v` after `expr-false` is definitely assigned, then the state of `v` after `expr` is definitely assigned.
  - Otherwise, the state of `v` after `expr` is not definitely assigned.

12.3.3.27 Anonymous method expressions

The definite assignment state of a parameter of an anonymous method (§14.5.15) is the same as for a parameter of a named method. That is, reference parameters and value parameters are initially definitely assigned and output parameters are initially unassigned. Furthermore, output parameters shall be definitely assigned before the anonymous method returns normally (§12.1.6).

The definite assignment state of an outer variable `v` on the control transfer to the block of an anonymous-method-expression is the same as the definite assignment state of `v` before the anonymous-method-expression. That is, definite assignment of outer variables is inherited from the context of the anonymous-method-expression. Within the block of an anonymous-method-expression, definite assignment evolves as in a normal block (§12.3.3).

The definite assignment state of a variable `v` after an anonymous-method-expression is the same as its definite assignment state before the anonymous-method-expression.

[Example: The example]

```csharp
debelte bool Filter(int i);
void F() {
    int max;
    // Error, max is not definitely assigned
    Filter f = delegate(int n) { return n < max; };  
    max = 5;
    DoWork(f);
}
```
generates a compile-time error since `max` is not definitely assigned where the anonymous method is declared. end example] [Example: The example]

```csharp
debelte void D();
void F() {
    int n;
    D d = delegate { n = 1; };
    d();
```
// Error, n is not definitely assigned
Console.WriteLine(n);
}
also generates a compile-time error since the assignment to n in the anonymous method has no affect on the
definite assignment state of n outside the anonymous method. end example]

12.3.3.28 Yield statements
For a yield return statement stmt of the form:

    yield return expr;

- A variable v has the same definite assignment state at the beginning of expr as at the beginning of stmt.
- If a variable v is definitely assigned at the end of expr, it is definitely assigned at the end point of stmt;
  otherwise, it is not definitely assigned at the end point of stmt.

12.4 Variable references
A variable-reference is an expression that is classified as a variable. A variable-reference denotes a storage
location that can be accessed both to fetch the current value and to store a new value.

    variable-reference:
      expression
[Note: In C and C++, a variable-reference is known as an lvalue. end note]

12.5 Atomicity of variable references
Reads and writes of the following data types shall be atomic: bool, char, byte, sbyte, short, ushort, uint, int, float, and reference types. In addition, reads and writes of enum types with an underlying type
in the previous list shall also be atomic. Reads and writes of other types, including long, ulong, double, and decimal, as well as user-defined types, need not be atomic. Aside from the library functions designed
for that purpose, there is no guarantee of atomic read-modify-write, such as in the case of increment or
decrement.
13. Conversions

A conversion enables an expression of one type to be treated as another type. Conversions can be implicit or explicit, and this determines whether an explicit cast is required. [Example: For instance, the conversion from type `int` to type `long` is implicit, so expressions of type `int` can implicitly be treated as type `long`. The opposite conversion, from type `long` to type `int`, is explicit, so an explicit cast is required.]

```csharp
int a = 123;
long b = a;  // implicit conversion from int to long
int c = (int) b;  // explicit conversion from long to int
```

Some conversions are defined by the language. Programs can also define their own conversions (§13.4).

### 13.1 Implicit conversions

The following conversions are classified as implicit conversions:

- Identity conversions
- Implicit numeric conversions
- Implicit enumeration conversions
- Implicit reference conversions
- Boxing conversions
- Implicit type parameter conversions
- Implicit constant expression conversions
- User-defined implicit conversions
- Implicit conversions from an anonymous method expression to a compatible delegate type
- Implicit conversion from a method group to a compatible delegate type
- Conversions from the `null` type (§11.2.7) to any nullable type
- Implicit nullable conversions
- Lifted user-defined implicit conversions

Implicit conversions can occur in a variety of situations, including function member invocations (§14.4.3), cast expressions (§14.6.6), and assignments (§14.14).

The pre-defined implicit conversions always succeed and never cause exceptions to be thrown. [Note: Properly designed user-defined implicit conversions should exhibit these characteristics as well. end note]

#### 13.1.1 Identity conversion

An identity conversion converts from any type to the same type. This conversion exists only such that an entity that already has a required type can be said to be convertible to that type.

#### 13.1.2 Implicit numeric conversions

The implicit numeric conversions are:

- From `sbyte` to `short`, `int`, `long`, `float`, `double`, or `decimal`. 
• From byte to short, ushort, int, uint, long, ulong, float, double, or decimal.
• From short to int, long, float, double, or decimal.
• From ushort to int, uint, long, ulong, float, double, or decimal.
• From int to long, float, double, or decimal.
• From uint to long, ulong, float, double, or decimal.
• From long to float, double, or decimal.
• From ulong to float, double, or decimal.
• From char to ushort, int, uint, long, ulong, float, double, or decimal.
• From float to double.

Conversions from int, uint, long or ulong to float and from long or ulong to double can cause a loss of precision, but will never cause a loss of magnitude. The other implicit numeric conversions never lose any information.

There are no implicit conversions to the char type, so values of the other integral types do not automatically convert to the char type.

13.1.3 Implicit enumeration conversions
An implicit enumeration conversion permits the decimal-integer-literal 0 to be converted to any enum-type.

13.1.4 Implicit reference conversions
The implicit reference conversions are:

• From any reference-type to object.
• From any class-type S to any class-type T, provided S is derived from T.
• From any class-type S to any interface-type T, provided S implements T.
• From any interface-type S to any interface-type T, provided S is derived from T.
• From an array-type S with an element type S_e to an array-type T with an element type T_e, provided all of the following are true:
  o S and T differ only in element type. In other words, S and T have the same number of dimensions.
  o An implicit reference conversion exists from S_e to T_e.
• From a one-dimensional array-type S[] to System.Collections.Generic.IList<S> and base interfaces of this interface.
• From a one-dimensional array-type S[] to System.Collections.Generic.IList<T> and base interfaces of this interface, provided there is an implicit reference conversion from S to T.
• From any array-type to System.Array.
• From any delegate-type to System.Delegate.
• From any array-type to any interface implemented by System.Array.
• From any delegate-type to System.ICloneable.
• From the null type (§11.2.7) to any reference-type.

For a type-parameter T that is known to be a reference type (§25.7), the following implicit reference conversions exist:
13 Conversions

- From T to its effective base class C, from T to any base class of C, and from T to any interface implemented by C.
- From T to an interface-type I in T’s effective interface set and from T to any base interface of I.
- From T to a type parameter U provided that T depends on U (§25.7). [Note: Since T is known to be a reference type, within the scope of T, the run-time type of U will always be a reference type, even if U is not known to be a reference type at compile-time. end note]
- From the null type (§11.2.7) to T.

The implicit reference conversions are those conversions between reference-types that can be proven to always succeed, and therefore require no checks at run-time.

Reference conversions, implicit or explicit, never change the referential identity of the object being converted. [Note: In other words, while a reference conversion can change the type of the reference, it never changes the type or value of the object being referred to. end note]

13.1.5 Boxing conversions

A boxing conversion permits any value-type to be implicitly converted to the type object or System.ValueType or to any interface-type implemented by the value-type, and any enum type to be implicitly converted to System.Enum as well. Boxing a value of a value-type consists of allocating an object instance and copying the value-type value into that instance. An enum can be boxed to the type System.Enum, since that is the direct base class for all enums (§21.4). A struct or enum can be boxed to the type System.ValueType, since that is the direct base class for all structs (§18.3.2) and a base class for all enums.

For a type-parameter T that is not known to be a reference type (§25.7), the following conversions involving T are considered to be boxing conversions at compile-time. At run-time, if T is a value type, the conversion is executed as a boxing conversion. At run-time, if T is a reference type, the conversion is executed as an implicit reference conversion or identity conversion.

- From T to its effective base class C, from T to any base class of C, and from T to any interface implemented by C. [Note: C will be one of the types System.Object, System.ValueType, or System.Enum (otherwise T would be known to be a reference type and §13.1.4 would apply instead of this clause). end note]
- From T to an interface-type I in T’s effective interface set and from T to any base interface of I.

Boxing conversions are described further in §11.3.1.

13.1.6 Implicit type parameter conversions

This clause details implicit conversions involving type parameters that are not classified as implicit reference conversions or implicit boxing conversions.

For a type-parameter T that is not known to be a reference type, there is an implicit conversion from T to a type parameter U provided T depends on U. At run-time, if T is a value type and U is a reference type, the conversion is executed as a boxing conversion. At run-time, if both T and U are value types, then T and U are necessarily the same type and no conversion is performed. At run-time, if T is a reference type, then U is necessarily also a reference type and the conversion is executed as an implicit reference conversion or identity conversion (§25.7).

13.1.7 Implicit constant expression conversions

An implicit constant expression conversion permits the following conversions:

- A constant-expression (§14.16) of type int can be converted to type sbyte, byte, short, ushort, uint, or ulong, provided the value of the constant-expression is within the range of the destination type.
A constant-expression of type long can be converted to type ulong, provided the value of the constant-expression is not negative.

13.1.8 User-defined implicit conversions
A user-defined implicit conversion consists of an optional standard implicit conversion, followed by execution of a user-defined implicit conversion operator, followed by another optional standard implicit conversion. The exact rules for evaluating user-defined conversions are described in §13.4.3.

13.2 Explicit conversions
The following conversions are classified as explicit conversions:

- All implicit conversions
- Explicit numeric conversions
- Explicit enumeration conversions
- Explicit reference conversions
- Explicit interface conversions
- Unboxing conversions
- Explicit type parameter conversions
- User-defined explicit conversions
- Explicit nullable conversions
- Lifted user-defined explicit conversions

Explicit conversions can occur in cast expressions (§14.6.6).

The set of explicit conversions includes all implicit conversions. [Note: This means that redundant cast expressions are allowed. end note]

The explicit conversions that are not implicit conversions are conversions that cannot be proven always to succeed, conversions that are known possibly to lose information, and conversions across domains of types sufficiently different to merit explicit notation.

13.2.1 Explicit numeric conversions
The explicit numeric conversions are the conversions from a numeric-type to another numeric-type for which an implicit numeric conversion (§13.1.2) does not already exist:

- From sbyte to byte, ushort, uint, ulong, or char.
- From byte to sbyte or char.
- From short to sbyte, byte, ushort, uint, ulong, or char.
- From ushort to sbyte, byte, short, or char.
- From int to sbyte, byte, short, ushort, uint, ulong, or char.
- From uint to sbyte, byte, short, ushort, int, or char.
- From long to sbyte, byte, short, ushort, int, uint, ulong, or char.
- From ulong to sbyte, byte, short, ushort, int, uint, long, or char.
- From char to sbyte, byte, or short.
- From float to sbyte, byte, short, ushort, int, uint, long, ulong, char, or decimal.
- From double to sbyte, byte, short, ushort, int, uint, long, ulong, char, float, or decimal.
• From decimal to sbyte, byte, short, ushort, int, uint, long, ulong, char, float, or double.

Because the explicit conversions include all implicit and explicit numeric conversions, it is always possible to convert from any numeric-type to any other numeric-type using a cast expression (§14.6.6).

The explicit numeric conversions possibly lose information or possibly cause exceptions to be thrown. An explicit numeric conversion is processed as follows:

• For a conversion from an integral type to another integral type, the processing depends on the overflow checking context (§14.5.12) in which the conversion takes place:
  - In a checked context, the conversion succeeds if the value of the source operand is within the range of the destination type, but throws a System.OverflowException if the value of the source operand is outside the range of the destination type.
  - In an unchecked context, the conversion always succeeds, and proceeds as follows.
    • If the source type is larger than the destination type, then the source value is truncated by discarding its “extra” most significant bits. The result is then treated as a value of the destination type.
    • If the source type is smaller than the destination type, then the source value is either sign-extended or zero-extended so that it is the same size as the destination type. Sign-extension is used if the source type is signed; zero-extension is used if the source type is unsigned. The result is then treated as a value of the destination type.
    • If the source type is the same size as the destination type, then the source value is treated as a value of the destination type.
• For a conversion from decimal to an integral type, the source value is rounded towards zero to the nearest integral value, and this integral value becomes the result of the conversion. If the resulting integral value is outside the range of the destination type, a System.OverflowException is thrown.
• For a conversion from float or double to an integral type, the processing depends on the overflow-checking context (§14.5.12) in which the conversion takes place:
  - In a checked context, the conversion proceeds as follows:
    • The value is rounded towards zero to the nearest integral value. If this integral value is within the range of the destination type, then this value is the result of the conversion.
    • Otherwise, a System.OverflowException is thrown.
  - In an unchecked context, the conversion always succeeds, and proceeds as follows.
    • The value is rounded towards zero to the nearest integral value. If this integral value is within the range of the destination type, then this value is the result of the conversion.
    • Otherwise, the result of the conversion is an unspecified value of the destination type.
• For a conversion from double to float, the double value is rounded to the nearest float value. This rounding may cause a non-zero value to be rounded to a zero value of the same sign. If the magnitude of the double value is too large to represent as a float, the result becomes positive infinity or negative infinity. If the double value is NaN, the result is also NaN.
• For a conversion from float or double to decimal, the source value is converted to decimal representation and rounded to the nearest number if required (§11.1.7). This rounding may cause a non-zero value to be rounded to zero. If the source value’s magnitude is too large to represent as a decimal, or that value is a NaN or infinity, yet the decimal representation does not support NaNs or infinities, respectively, a System.OverflowException is thrown.
• For a conversion from decimal to float or double, the decimal value is rounded to the nearest double or float value. However, if the value being converted is not within the range of the destination type, a System.OverflowException is thrown.
13.2.2 Explicit enumeration conversions

The explicit enumeration conversions are:

- From sbyte, byte, short, ushort, int, uint, long, ulong, char, float, double, or decimal to any enum-type.
- From any enum-type to sbyte, byte, short, ushort, int, uint, long, ulong, char, float, double, or decimal.
- From any enum-type to any other enum-type.

An explicit enumeration conversion between two types is processed by treating any participating enum-type as the underlying type of that enum-type, and then performing an implicit or explicit numeric conversion between the resulting types. [Example: Given an enum-type E with and underlying type of int, a conversion from E to byte is processed as an explicit numeric conversion (§13.2.1) from int to byte, and a conversion from byte to E is processed as an implicit numeric conversion (§13.1.2) from byte to int. end example]

13.2.3 Explicit reference conversions

The explicit reference conversions are:

- From object to any reference-type.
- From any class-type S to any class-type T, provided S is a base class of T.
- From any class-type S to any interface-type T, provided S is not sealed and provided S does not implement T.
- From any interface-type S to any class-type T, provided T is not sealed or provided T implements S.
- From any interface-type S to any interface-type T, provided S is not derived from T.
- From an array-type S with an element type S_e to an array-type T with an element type T_e, provided all of the following are true:
  - S and T differ only in element type. (In other words, S and T have the same number of dimensions.)
  - An explicit reference conversion exists from S_e to T_e.
- From System.Array and the interfaces it implements, to any array-type.
- From System.Delegate and the interfaces it implements, to any delegate-type.
- From a one-dimensional array-type S[] to System.Collections.Generic_IList<T> and its base interfaces, provided there is an explicit reference conversion from S to T.
- From System.Collections.Generic_IList<T> and its base interfaces to a one-dimensional array-type S[], provided there is an implicit or explicit reference conversion from S[] to System.Collections.Generic_IList<T>. This is precisely when either S and T are the same type or there is an implicit or explicit reference conversion from S to T.

For a type-parameter T that is known to be a reference type (§25.7), the following explicit reference conversions exist:

- From the effective base class C of T to T and from any base class of C to T.
- From any interface-type to T.
- From T to any interface-type I provided there isn’t already an implicit reference conversion from T to I.
- From a type-parameter U to T provided that T depends on U (§25.7). [Note: Since T is known to be a reference type, within the scope of T, the run-time type of U will always be a reference type, even if U is not known to be a reference type at compile-time. end note]
The explicit reference conversions are those conversions between *reference-types* that require run-time checks to ensure they are correct.

For an explicit reference conversion to succeed at run-time, the value of the source operand shall be `null`, or the runtime type of the object referenced by the source operand shall be a type that can be converted to the destination type by an implicit reference conversion (§13.1.4). If an explicit reference conversion fails, a `System.InvalidCastException` is thrown.

Reference conversions, implicit or explicit, never change the referential identity of the object being converted. [Note: In other words, while a reference conversion can change the type of the reference, it never changes the type or value of the object being referred to. end note]

### 13.2.4 Unboxing conversions

An unboxing conversion permits an explicit conversion from type `object` or `System.ValueType` to any *value-type*, or from any *interface-type* to any *value-type* that implements the *interface-type*, and from the type `System.Enum` to any enumeration type. An unboxing operation consists of first checking that the object instance is a boxed value of the given *value-type* or enumeration type, and then copying the value out of the instance. An enum can be unboxed from the type `System.Enum`, since that is the direct base class for all enum types (§21.4). A struct or enum can be unboxed from the type `System.ValueType`, since that is the direct base class for all structs (§18.3.2) and a base class for all enums.

For a type-parameter $T$ that is *not* known to be a reference type (§25.7), the following conversions involving $T$ are considered to be unboxing conversions at compile-time. At run-time, if $T$ is a value type, the conversion is executed as an unboxing conversion. At run-time, if $T$ is a reference type, the conversion is executed as an explicit reference conversion or identity conversion.

- From the effective base class $C$ of $T$ to $T$ and from any base class of $C$ to $T$. [Note: $C$ will be one of the types `System.Object`, `System.ValueType`, or `System.Enum` (otherwise $T$ would be known to be a reference type and §13.2.3 would apply instead of this clause). end note]
- From any *interface-type* to $T$.

Unboxing conversions are described further in §11.3.2.

### 13.2.5 Explicit type parameter conversions

This clause details explicit conversions involving type parameters that are not classified as explicit reference conversions or explicit unboxing conversions.

For a type-parameter $T$ that is *not* known to be a reference type (§25.7), the following explicit conversions exist:

- From $T$ to any *interface-type* $I$ provided there is not already an implicit conversion from $T$ to $I$. This conversion consists of an implicit boxing conversion (§13.1.5) from $T$ to `object` followed by an explicit reference conversion from `object` to $I$. At run-time, if $T$ is a value type, the conversion is executed as a boxing conversion followed by an explicit reference conversion. At run-time, if $T$ is a reference type, the conversion is executed as an explicit reference conversion.

- From a type parameter $U$ to $T$ provided that $T$ depends on $U$ (§25.7). At run-time, if $T$ is a value type and $U$ is a reference type, the conversion is executed as an unboxing conversion. At run-time, if both $T$ and $U$ are value types, then $T$ and $U$ are necessarily the same type and no conversion is performed. At run-time, if $T$ is a reference type, then $U$ is necessarily also a reference type and the conversion is executed as an explicit reference conversion or identity conversion.

### 13.2.6 User-defined explicit conversions

A user-defined explicit conversion consists of an optional standard explicit conversion, followed by execution of a user-defined implicit or explicit conversion operator, followed by another optional standard explicit conversion. The exact rules for evaluating user-defined conversions are described in §13.4.4.
13.3 Standard conversions
The standard conversions are those pre-defined conversions that can occur as part of a user-defined conversion.

13.3.1 Standard implicit conversions
The following implicit conversions are classified as standard implicit conversions:
- Identity conversions (§13.1.1)
- Implicit numeric conversions (§13.1.2)
- Implicit reference conversions (§13.1.4)
- Boxing conversions (§13.1.5)
- Implicit type parameter conversions (§13.1.6)
- Implicit constant expression conversions (§13.1.7)
- Implicit nullable conversions (§13.7.2)

The standard implicit conversions specifically exclude user-defined implicit conversions.

13.3.2 Standard explicit conversions
The standard explicit conversions are all standard implicit conversions plus the subset of the explicit conversions for which an opposite standard implicit conversion exists.  

[Note: In other words, if a standard implicit conversion exists from a type $A$ to a type $B$, then a standard explicit conversion exists from type $A$ to type $B$ and from type $B$ to type $A$. end note]

13.4 User-defined conversions
C# allows the pre-defined implicit and explicit conversions to be augmented by user-defined conversions. User-defined conversions are introduced by declaring conversion operators (§17.9.3) in class and struct types.

13.4.1 Permitted user-defined conversions
C# permits only certain user-defined conversions to be declared. In particular, it is not possible to redefine an already existing implicit or explicit conversion.

The restrictions that apply to user-defined conversions are specified in §17.9.3.

13.4.2 Evaluation of user-defined conversions
A user-defined conversion converts a value from its type, called the source type, to another type, called the target type. Evaluation of a user-defined conversion centers on finding the most specific user-defined conversion operator for the particular source and target types. This determination is broken into several steps:
- Finding the set of classes and structs from which user-defined conversion operators will be considered. This set consists of the source type and its base classes and the target type and its base classes (with the implicit assumptions that only classes and structs can declare user-defined operators, and that non-class types have no base classes). Trailing ? modifiers, if any, are removed from the source and target types before determining the set of types from which user-defined conversion operators will be considered. For example, when converting from a type $S?$ to a type $T?$, the set of types from which user-defined conversion operators will be considered consists of $S$ and $T$.
- From that set of types, determining which user-defined conversion operators are applicable. For a conversion operator to be applicable, it shall be possible to perform a standard conversion (§13.3) from the source type to the operand type of the operator, and it shall be possible to perform a standard
conversion from the result type of the operator to the target type. When the source and target types are both nullable, the set of applicable conversion operators includes not just user-defined conversion operators but also lifted conversion operators (§13.7.3). If the set of applicable user-defined conversion operators is empty then there is no user-defined conversion from the source type to the target type.

- From the set of applicable user-defined operators, determining which operator is unambiguously the most specific. In general terms, the most specific operator is the operator whose operand type is “closest” to the source type and whose result type is “closest” to the target type. The exact rules for establishing the most specific user-defined conversion operator are defined in the following subclauses.

For the purposes of overload resolution, a user-defined conversion from the source type to the target type exists if and only if the set of applicable user-defined conversion operators is non-empty. If the set of applicable operators is non-empty but does not contain a unique most specific operator, the user-defined conversion is deemed to exist even though application of the conversion will always produce a compile-time error.

Once a most specific user-defined conversion operator has been identified, the actual execution of the user-defined conversion involves up to three steps:

- First, if required, performing a standard conversion from the source type to the operand type of the user-defined conversion operator.
- Next, invoking the user-defined conversion operator to perform the conversion.
- Finally, if required, performing a standard conversion from the result type of the user-defined conversion operator to the target type.

Evaluation of a user-defined conversion never involves more than one user-defined conversion operator. In other words, a conversion from type S to type T will never first execute a user-defined conversion from S to X and then execute a user-defined conversion from X to T.

Exact definitions of evaluation of user-defined implicit or explicit conversions are given in the following subclauses. The definitions make use of the following terms:

- If a standard implicit conversion (§13.3.1) exists from a type A to a type B, and if neither A nor B are interface-types, then A is said to be encompassed by B, and B is said to encompass A.
- The **most encompassing type** in a set of types is the one type that encompasses all other types in the set. If no single type encompasses all other types, then the set has no most encompassing type. In more intuitive terms, the most encompassing type is the “largest” type in the set—the one type to which each of the other types can be implicitly converted.
- The **most encompassed type** in a set of types is the one type that is encompassed by all other types in the set. If no single type is encompassed by all other types, then the set has no most encompassed type. In more intuitive terms, the most encompassed type is the “smallest” type in the set—the one type that can be implicitly converted to each of the other types.

### 13.4.3 User-defined implicit conversions

A user-defined implicit conversion from type S to type T is processed as follows:

- Determine the types S0 and T0 that result from removing the trailing ? modifiers, if any, from S and T.
- Find the set of types, D, from which user-defined conversion operators will be considered. This set consists of S0 (if S0 is a class or struct), the base classes of S0 (if S0 is a class), and T0 (if T0 is a class or struct).
- Find the set of applicable conversion operators, U. This set consists of the user-defined and, if S and T are both nullable, lifted implicit conversion operators (§13.7.3) declared by the classes or structs in D that convert from a type encompassing S to a type encompassed by T. If U is empty, there is no conversion, and a compile-time error occurs.
13.4.4 User-defined explicit conversions

A user-defined explicit conversion from type S to type T is processed as follows:

- Determine the types S0 and T0 that result from removing the trailing ? modifiers, if any, from S and T.
- Find the set of types, D, from which user-defined conversion operators will be considered. This set consists of S0 (if S0 is a class or struct), the base classes of S0 (if S0 is a class), T0 (if T0 is a class or struct), and the base classes of T0 (if T0 is a class).
- Find the set of applicable conversion operators, U. This set consists of the user-defined and, if S and T are both nullable, lifted implicit or explicit conversion operators (§13.7.3) declared by the classes or structs in D that convert from a type encompassing or encompassed by S to a type encompassing or encompassed by T. If U is empty, there is no conversion, and a compile-time error occurs.
- Find the most specific source type, SX, of the operators in U:
  - If any of the operators in U convert from S, then SX is S.
  - Otherwise, SX is the most encompassed type in the combined set of source types of those operators. If exactly one most encompassed type cannot be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific target type, TX, of the operators in U:
  - If any of the operators in U convert to T, then TX is T.
  - Otherwise, TX is the most encompassing type in the combined set of target types of those operators. If exactly one most encompassing type cannot be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific conversion operator:
  - If U contains exactly one user-defined conversion operator that converts from SX to TX, then this is the most specific conversion operator.
  - Otherwise, if U contains exactly one lifted conversion operator that converts from SX to TX, then this is the most specific conversion operator.
  - Otherwise, the conversion is ambiguous and a compile-time error occurs.
- Finally, apply the conversion:
  - If S is not SX, then a standard implicit conversion from S to SX is performed.
  - The most specific conversion operator is invoked to convert from SX to TX.
  - If TX is not T, then a standard implicit conversion from TX to T is performed.
Otherwise, if any of the operators in $U$ convert to types that are encompassed by $T$, then $TX$ is the most encompassing type in the combined set of target types of those operators. If exactly one most encompassing type cannot be found, then the conversion is ambiguous and a compile-time error occurs.

Otherwise, $TX$ is the most encompassed type in the combined set of target types of the operators in $U$. If exactly one most encompassed type cannot be found, then the conversion is ambiguous and a compile-time error occurs.

• Find the most specific conversion operator:
  o If $U$ contains exactly one user-defined conversion operator that converts from $SX$ to $TX$, then this is the most specific conversion operator.
  o Otherwise, if $U$ contains exactly one lifted conversion operator that converts from $SX$ to $TX$, then this is the most specific conversion operator.
  o Otherwise, the conversion is ambiguous and a compile-time error occurs.

• Finally, apply the conversion:
  o If $S$ is not $SX$, then a standard explicit conversion from $S$ to $SX$ is performed.
  o The most specific conversion operator is invoked to convert from $SX$ to $TX$.
  o If $TX$ is not $T$, then a standard explicit conversion from $TX$ to $T$ is performed.

13.5 Anonymous method conversions

An implicit conversion (§13.1) exists from an anonymous-method-expression to any compatible delegate type. If $D$ is a delegate type, and $A$ is an anonymous-method-expression, then $D$ is compatible with $A$ if and only if the following two conditions are met.

• First, the parameter types of $D$ shall be compatible with $A$:
  o If $A$ does not contain an anonymous-method-signature, then $D$ can have zero or more parameters of any type, as long as no parameter of $D$ has the out parameter modifier.
  o If $A$ has an anonymous-method-signature, then $D$ shall have the same number of parameters and each parameter of $A$ shall be compatible with the corresponding parameter of $D$. A parameter of $A$ is considered compatible with a parameter of $D$ if they are both of the same type and the presence or absence of the ref or out modifier on the parameter of $A$ matches the corresponding parameter of $D$. Whether the final parameter of $D$ is a parameter-array is not considered when determining the compatibility of $A$ and $D$. A parameter which has the parameter-array modifier is compatible with a parameter without the parameter-array modifier if they are both of the same type.

• Second, the return type of $D$ shall be compatible with $A$. For these rules, $A$ is not considered to contain the block of any other anonymous methods:
  o If $D$ is declared with a void return type, then any return statement contained in $A$ shall not specify an expression.
  o If $D$ is declared with a return type of $R$, then any return statement contained in $A$ shall specify an expression which is implicitly convertible (§13.1) to $R$. Furthermore, the end-point of the block of $A$ shall not be reachable. [Note: The block of an anonymous-method-expression is always considered reachable, even if it is contained in a statement that is unreachable. See §15.1. end note]

Besides the implicit conversions to compatible delegate types, no other conversions exist from an anonymous-method-expression, not even to the type object.

[Example: The following examples illustrate these rules:

delegate void D(int x);
A delegate-creation-expression (§14.5.10.3) can be used as an alternate syntax for converting an anonymous method to a delegate type.

13.6 Method group conversions

Similar to the implicit anonymous method conversions described in §13.5, an implicit conversion exists from a method group (§14.1) to a compatible delegate type. If D is a delegate type, and E is an expression that is classified as a method group, then D is compatible with E if and only if E contains at least one method that is applicable in its normal form (§14.4.2.1) to any argument list (§14.4.1) having types and modifiers matching the parameter types and modifiers of D.

The compile-time application of the conversion from E to D is the same as the compile-time processing of the delegate creation expression new D(E) (§14.5.10.3). Note that the existence of an implicit conversion from E to D just indicates that the set of applicable methods is not empty, but does not guarantee that the compile-time application of the conversion will succeed without error.

[Example: In the following code]

```csharp
using System;
using System.Windows.Forms;

class AlertDialog
{
    Label message = new Label();
    Button okButton = new Button();
    Button cancelButton = new Button();
    public AlertDialog()
    {
        okButton.Click += new EventHandler(OkClick);
        cancelButton.Click += new EventHandler(CancelClick);
    }
}
```
13 Conversions

```csharp
void OkClick(object sender, EventArgs e) {
    ...
}

void CancelClick(object sender, EventArgs e) {
    ...
}
```

The constructor creates two delegate instances using the `new` operator. Implicit method group conversions permit this to be shortened to

```csharp
public AlertDialog() {
    okButton.Click += OkClick;
    cancelButton.Click += CancelClick;
}
```

As with all other implicit and explicit conversions, the cast operator can be used to explicitly perform a particular conversion. *Example:* Thus, the example

```csharp
object obj = new EventHandler(myDialog.OkClick);
```

could instead be written

```csharp
object obj = (EventHandler)myDialog.OkClick;
```

*end example*

Although method groups and anonymous method expressions can influence overload resolution, they do not participate in type inferencing (§25.6.4).

13.7 Conversions involving nullable types

The following terms are used in the subsequent sections:

- The term *wrapping* denotes the process of packaging a value, of type \( T \), in an instance of type \( T? \). A value \( x \) of type \( T \) is wrapped to type \( T? \) by evaluating the expression `new T?(x)`.

- The term *unwrapping* denotes the process of obtaining the value, of type \( T \), contained in an instance of type \( T? \). A value \( x \) of type \( T? \) is unwrapped to type \( T \) by evaluating the expression `x.Value`. Attempting to unwrap a null instance causes a `System.InvalidOperationException` to be thrown.

13.7.1 Null type conversions

An implicit conversion exists from the `null` type (§11.2.7) to any nullable type. This conversion produces the null value (§12.2) of the given nullable type.

13.7.2 Nullable conversions

*Nullable conversions* permit predefined conversions that operate on non-nullable value types to also be used with nullable forms of those types. For each of the predefined implicit or explicit conversions that convert from a non-nullable value type \( S \) to a non-nullable value type \( T \) (§13.1.1, §13.1.2, §13.1.3, §13.1.6, §13.2.1, and §13.2.2), the following nullable conversions exist:

- An implicit or explicit conversion from \( S? \) to \( T? \).
- An implicit or explicit conversion from \( S? \) to \( T \).
- An explicit conversion from \( S? \) to \( T \).

A nullable conversion is itself classified as an implicit or explicit conversion.

Certain nullable conversions are classified as standard conversions and can occur as part of a user-defined conversion. Specifically, all implicit nullable conversions are classified as standard implicit conversions.
(§13.1.1), and those explicit nullable conversions that satisfy the requirements of §13.3.2 are classified as standard explicit conversions.

Evaluation of a nullable conversion based on an underlying conversion from \( S \) to \( T \) proceeds as follows:

- If the nullable conversion is from \( S? \) to \( T? \):
  - If the source value is null (\( \text{HasValue} \) property is false), the result is the null value of type \( T? \).
  - Otherwise, the conversion is evaluated as an unwrapping from \( S? \) to \( S \), followed by the underlying conversion from \( S \) to \( T \), followed by a wrapping from \( T \) to \( T? \).

- If the nullable conversion is from \( S \) to \( T? \), the conversion is evaluated as the underlying conversion from \( S \) to \( T \) followed by a wrapping from \( T \) to \( T? \).

- If the nullable conversion is from \( S? \) to \( T \), the conversion is evaluated as an unwrapping from \( S? \) to \( S \) followed by the underlying conversion from \( S \) to \( T \).

13.7.3 Lifted conversions

Given a user-defined conversion operator that converts from a non-nullable value type \( S \) to a non-nullable value type \( T \), a \textit{lifted conversion operator} exists that converts from \( S? \) to \( T? \). This lifted conversion operator performs an unwrapping from \( S? \) to \( S \) followed by the user-defined conversion from \( S \) to \( T \) followed by a wrapping from \( T \) to \( T? \), except that a null valued \( S? \) converts directly to a null valued \( T? \).

A lifted conversion operator has the same implicit or explicit classification as its underlying user-defined conversion operator.
14. Expressions

An expression is a sequence of operators and operands. This clause defines the syntax, order of evaluation of operands and operators, and meaning of expressions.

14.1 Expression classifications

An expression is classified as one of the following:

- A value. Every value has an associated type.
- A variable. Every variable has an associated type, namely the declared type of the variable.
- A namespace. An expression with this classification can only appear as the left-hand side of a *member-access* (§14.5.4). In any other context, an expression classified as a namespace causes a compile-time error.
- A type. An expression with this classification can only appear as the left-hand side of a *member-access* (§14.5.4), or as an operand for the *as* operator (§14.9.11), the *is* operator (§14.9.10), or the *typeof* operator (§14.5.11). In any other context, an expression classified as a type causes a compile-time error.
- A method group, which is a set of overloaded methods resulting from a member lookup (§14.3). A method group can have an associated instance expression. When an instance method is invoked, the result of evaluating the instance expression becomes the instance represented by *this* (§14.5.7). A method group can be used in an *invocation-expression* (§14.5.5), used in a *delegate-creation-expression* (§14.5.10.3), or implicitly converted to a compatible delegate type. In any other context, an expression classified as a method group causes a compile-time error.
- An anonymous method. An expression with this classification can be used in a *delegate-creation-expression* (§14.5.10.3) or implicitly converted to a compatible delegate type. In any other context, an expression classified as an anonymous method causes a compile-time error.
- A property access. Every property access has an associated type, namely the type of the property. Furthermore, a property access can have an associated instance expression. When an accessor (the *get* or *set* block) of an instance property access is invoked, the result of evaluating the instance expression becomes the instance represented by *this* (§14.5.7).
- An event access. Every event access has an associated type, namely the type of the event. Furthermore, an event access can have an associated instance expression. An event access can appear as the left-hand operand of the *+=* and *-=* operators (§14.14.3). In any other context, an expression classified as an event access causes a compile-time error.
- An indexer access. Every indexer access has an associated type, namely the element type of the indexer. Furthermore, an indexer access has an associated instance expression and an associated argument list. When an accessor (the *get* or *set* block) of an indexer access is invoked, the result of evaluating the instance expression becomes the instance represented by *this* (§14.5.7), and the result of evaluating the argument list becomes the parameter list of the invocation.
- Nothing. This occurs when the expression is an invocation of a method with a return type of *void*. An expression classified as nothing is only valid in the context of a *statement-expression* (§15.6).

The final result of an expression is never a namespace, type, method group, anonymous method, or event access. Rather, as noted above, these categories of expressions are intermediate constructs that are only permitted in certain contexts.
A property access or indexer access is always reclassified as a value by performing an invocation of the get-accessor or the set-accessor. The particular accessor is determined by the context of the property or indexer access: If the access is the target of an assignment, the set-accessor is invoked to assign a new value (§14.14.1). Otherwise, the get-accessor is invoked to obtain the current value (§14.1.1).

**14.1.1 Values of expressions**

Most of the constructs that involve an expression ultimately require the expression to denote a value. In such cases, if the actual expression denotes a namespace, a type, or nothing, a compile-time error occurs. However, if the expression denotes a property access, an indexer access, or a variable, the value of the property, indexer, or variable is implicitly substituted:

- The value of a variable is simply the value currently stored in the storage location identified by the variable. A variable shall be considered definitely assigned (§12.3) before its value can be obtained, or otherwise a compile-time error occurs.
- The value of a property access expression is obtained by invoking the get-accessor of the property. If the property has no get-accessor, a compile-time error occurs. Otherwise, a function member invocation (§14.4.3) is performed, and the result of the invocation becomes the value of the property access expression.
- The value of an indexer access expression is obtained by invoking the get-accessor of the indexer. If the indexer has no get-accessor, a compile-time error occurs. Otherwise, a function member invocation (§14.4.3) is performed with the argument list associated with the indexer access expression, and the result of the invocation becomes the value of the indexer access expression.

**14.2 Operators**

Expressions are constructed from operands and operators. The operators of an expression indicate which operations to apply to the operands. [Example: Examples of operators include +, -, *, /, and new. Examples of operands include literals, fields, local variables, and expressions. end example]

There are three kinds of operators:

- Unary operators. The unary operators take one operand and use either prefix notation (such as –x) or postfix notation (such as x++).
- Binary operators. The binary operators take two operands and all use infix notation (such as x + y).
- Ternary operator. Only one ternary operator, ?, exists; it takes three operands and uses infix notation (c ? x : y).

The order of evaluation of operators in an expression is determined by the precedence and associativity of the operators (§14.2.1).

The order in which operands in an expression are evaluated, is left to right. [Example: In F(i) + G(i++) * H(i), method F is called using the old value of i, then method G is called with the old value of i, and, finally, method H is called with the new value of i. This is separate from and unrelated to operator precedence. end example]

Certain operators can be overloaded. Operator overloading (§14.2.2) permits user-defined operator implementations to be specified for operations where one or both of the operands are of a user-defined class or struct type.

**14.2.1 Operator precedence and associativity**

When an expression contains multiple operators, the precedence of the operators controls the order in which the individual operators are evaluated. [Note: For example, the expression x + y * z is evaluated as x + (y * z) because the * operator has higher precedence than the binary + operator. end note] The precedence of an operator is established by the definition of its associated grammar production. [Note: For
example, an *additive-expression* consists of a sequence of *multiplicative-expressions* separated by + or − operators, thus giving the + and − operators lower precedence than the *, /, and % operators. *end note*

The following table summarizes all operators in order of precedence from highest to lowest:

<table>

</tr>
</tbody>
</table>

When an operand occurs between two operators with the same precedence, the *associativity* of the operators controls the order in which the operations are performed:

- Except for the assignment operators and the null coalescing operator, all binary operators are *left-associative*, meaning that operations are performed from left to right. *Example: x + y + z* is evaluated as *(x + y) + z*. *end example*
- The assignment operators, null coalescing operator and the conditional operator (?) are *right-associative*, meaning that operations are performed from right to left. *Example: x = y = z* is evaluated as *x = (y = z)*. *end example*

Precedence and associativity can be controlled using parentheses. *Example: x + y * z* first multiplies y by z and then adds the result to x, but *(x + y) * z* first adds x and y and then multiplies the result by z. *end example*

### 14.2.2 Operator overloading

All unary and binary operators have predefined implementations that are automatically available in any expression. In addition to the predefined implementations, user-defined implementations can be introduced by including *operator* declarations (§17.9) in classes and structs. User-defined operator implementations always take precedence over predefined operator implementations: Only when no applicable user-defined operators implementations exist are the predefined operator implementations considered, as described in §14.2.3 and §14.2.4.

The *overloadable unary operators* are:
+  -  !  ~  ++  --  true  false

[Note: Although true and false are not used explicitly in expressions (and therefore are not included in the precedence table in §14.2.1), they are considered operators because they are invoked in several expression contexts: Boolean expressions (§14.17) and expressions involving the conditional operator (§14.13) and conditional logical operators (§14.11). end note]

The overaddable binary operators are:

+  -  *  /  %  &  |  ^  <<  >>  ==  !=  >  <  >=  <=

Only the operators listed above can be overloaded. In particular, it is not possible to overload member access, method invocation, or the =, &&, ||, ??, ??, checked, unchecked, new, typeof, as, and is operators.

When a binary operator is overloaded, the corresponding assignment operator, if any, is also implicitly overloaded. [Example: An overload of operator * is also an overload of operator *=. This is described further in §14.14. end example] The assignment operator itself (=) cannot be overloaded. An assignment always performs a simple bit-wise copy of a value into a variable.

Cast operations, such as (T)x, are overloaded by providing user-defined conversion operators (§13.4).

Element access, such as a[x], is not considered an overaddable operator. Instead, user-defined indexing is supported through indexers (§17.8).

In expressions, operators are referenced using operator notation, and in declarations, operators are referenced using functional notation. The following table shows the relationship between operator and functional notations for unary and binary operators. In the first entry, op denotes any overaddable unary prefix operator. In the second entry, op denotes the unary postfix ++ and -- operators. In the third entry, op denotes any overaddable binary operator. [Note: For an example of overloading the ++ and -- operators see §17.9.1. end note]

<table>
<thead>
<tr>
<th>Operator notation</th>
<th>Functional notation</th>
</tr>
</thead>
<tbody>
<tr>
<td>op x</td>
<td>operator op(x)</td>
</tr>
<tr>
<td>x op</td>
<td>operator op(x)</td>
</tr>
<tr>
<td>x op y</td>
<td>operator op(x, y)</td>
</tr>
</tbody>
</table>

User-defined operator declarations always require at least one of the parameters to be of the class or struct type that contains the operator declaration. [Note: Thus, it is not possible for a user-defined operator to have the same signature as a predefined operator. end note]

User-defined operator declarations cannot modify the syntax, precedence, or associativity of an operator. [Example: The / operator is always a binary operator, always has the precedence level specified in §14.2.1, and is always left-associative. end example]

[Note: While it is possible for a user-defined operator to perform any computation it pleases, implementations that produce results other than those that are intuitively expected are strongly discouraged. For example, an implementation of operator == should compare the two operands for equality and return an appropriate bool result. end note]

The descriptions of individual operators in §14.5 through §14.14 specify the predefined implementations of the operators and any additional rules that apply to each operator. The descriptions make use of the terms unary operator overload resolution, binary operator overload resolution, numeric promotion, and lifted operators definitions of which are found in the following subclauses.

14.2.3 Unary operator overload resolution

An operation of the form op x or x op, where op is an overaddable unary operator, and x is an expression of type X, is processed as follows:
• The set of candidate user-defined operators provided by \( X \) for the operation \( \text{operator } op(x) \) is determined using the rules of §14.2.5.

• If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the predefined unary \( \text{operator } op \) implementations become the set of candidate operators for the operation. If type \( X \) is not an enum type, then any predefined unary operator with a parameter type that is an enum type is removed from consideration. The predefined implementations of a given operator are specified in the description of the operator (§14.5 and §14.5.14).

• The overload resolution rules of §14.4.2 are applied to the set of candidate operators to select the best operator with respect to the argument list \((x)\), and this operator becomes the result of the overload resolution process. If overload resolution fails to select a single best operator, a compile-time error occurs.

14.2.4 Binary operator overload resolution
An operation of the form \( x \op y \), where \( \op \) is an overloadable binary operator, \( x \) is an expression of type \( X \), and \( y \) is an expression of type \( Y \), is processed as follows:

• The set of candidate user-defined operators provided by \( X \) and \( Y \) for the operation \( \text{operator } op(x, y) \) is determined. The set consists of the union of the candidate operators provided by \( X \) and the candidate operators provided by \( Y \), each determined using the rules of §14.2.5. If \( X \) and \( Y \) are the same type, or if \( X \) and \( Y \) are derived from a common base type, then shared candidate operators only occur in the combined set once.

• If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the predefined binary \( \text{operator } op \) implementations become the set of candidate operators for the operation. If neither \( X \) nor \( Y \) is an enum type, then any predefined binary operator with a parameter type that is an enum type is removed from consideration. Similarly, if neither \( X \) nor \( Y \) is a delegate type, then any predefined binary operator with a parameter type that is a delegate type is removed from consideration. The predefined implementations of a given operator are specified in the description of the operator (§14.7 through §14.14).

• The overload resolution rules of §14.4.2 are applied to the set of candidate operators to select the best operator with respect to the argument list \((x, y)\), and this operator becomes the result of the overload resolution process. If overload resolution fails to select a single best operator, a compile-time error occurs.

14.2.5 Candidate user-defined operators
Given a type \( T \) and an operation \( \text{operator } op(A) \), where \( \op \) is an overloadable operator and \( A \) is an argument list, the set of candidate user-defined operators provided by \( T \) for \( \text{operator } op(A) \) is determined as follows:

• Determine the type \( T_0 \) that results from removing the trailing \(?\) modifiers, if any, from \( T \).

• For all \( \text{operator } op \) declarations in \( T_0 \), if at least one operator is applicable (§14.4.2.1) with respect to the argument list \( A \), then the set of candidate operators consists of all applicable \( \text{operator } op \) declarations in \( T_0 \). The lifted forms of the operators (§14.2.7) declared in \( T_0 \) are considered to also be declared by \( T_0 \).

• Otherwise, if \( T_0 \) is \texttt{object}, the set of candidate operators is empty.

• Otherwise, the set of candidate operators provided by \( T_0 \) is the set of candidate operators provided by the direct base class of \( T_0 \).

14.2.6 Numeric promotions
This subclause is informative.
Numeric promotion consists of automatically performing certain implicit conversions of the operands of the predefined unary and binary numeric operators. Numeric promotion is not a distinct mechanism, but rather an effect of applying overload resolution to the predefined operators. Numeric promotion specifically does not affect evaluation of user-defined operators, although user-defined operators can be implemented to exhibit similar effects.

As an example of numeric promotion, consider the predefined implementations of the binary * operator:

```csharp
int operator *(int x, int y);
uint operator *(uint x, uint y);
long operator *(long x, long y);
ulong operator *(ulong x, ulong y);
void operator *(long x, ulong y);
void operator *(ulong x, long y);
float operator *(float x, float y);
double operator *(double x, double y);
declaring operator *(decimal x, decimal y);
```

When overload resolution rules (§14.4.2) are applied to this set of operators, the effect is to select the first of the operators for which implicit conversions exist from the operand types. [Example: For the operation b * s, where b is a byte and s is a short, overload resolution selects operator *(int, int) as the best operator. Thus, the effect is that b and s are converted to int, and the type of the result is int. Likewise, for the operation i * d, where i is an int and d is a double, overload resolution selects operator *(double, double) as the best operator. end example]

End of informative text.

14.2.6.1 Unary numeric promotions

This subclause is informative.

Unary numeric promotion occurs for the operands of the predefined +, –, and ~ unary operators. Unary numeric promotion simply consists of converting operands of type sbyte, byte, short, ushort, or char to type int. Additionally, for the unary – operator, unary numeric promotion converts operands of type uint to type long.

End of informative text.

14.2.6.2 Binary numeric promotions

This subclause is informative.

Binary numeric promotion occurs for the operands of the predefined +, –, *, /, %, &., |., ^, &=, |&=, ^=, <<=, >>=, and <= binary operators. Binary numeric promotion implicitly converts both operands to a common type which, in case of the non-relational operators, also becomes the result type of the operation. Binary numeric promotion consists of applying the following rules, in the order they appear here:

- If either operand is of type decimal, the other operand is converted to type decimal, or a compile-time error occurs if the other operand is of type float or double.
- Otherwise, if either operand is of type double, the other operand is converted to type double.
- Otherwise, if either operand is of type float, the other operand is converted to type float.
- Otherwise, if either operand is of type ulong, the other operand is converted to type ulong, or a compile-time error occurs if the other operand is of type sbyte, short, int, or long.
- Otherwise, if either operand is of type long, the other operand is converted to type long.
- Otherwise, if either operand is of type uint and the other operand is of type sbyte, short, or int, both operands are converted to type long.
- Otherwise, if either operand is of type uint, the other operand is converted to type uint.
- Otherwise, both operands are converted to type int.
Note: The first rule disallows any operations that mix the decimal type with the double and float types. The rule follows from the fact that there are no implicit conversions between the decimal type and the double and float types. end note

Note: Also note that it is not possible for an operand to be of type ulong when the other operand is of a signed integral type. The reason is that no integral type exists that can represent the full range of ulong as well as the signed integral types. end note

In both of the above cases, a cast expression can be used to explicitly convert one operand to a type that is compatible with the other operand.

Example: In the following code

```
decimal AddPercent(decimal x, double percent) {
    return x * (1.0 + percent / 100.0);
}
```

a compile-time error occurs because a decimal cannot be multiplied by a double. The error is resolved by explicitly converting the second operand to decimal, as follows:

```
decimal AddPercent(decimal x, double percent) {
    return x * (decimal)(1.0 + percent / 100.0);
}
```

end example

14.2.7 Lifted operators

Lifted operators permit predefined and user-defined operators that operate on non-nullable value types to also be used with nullable forms of those types. Lifted operators are constructed from predefined and user-defined operators that meet certain requirements, as described in the following:

- For the unary operators
  
  +  ++  -  --  !  ~

  a lifted form of an operator exists if the operand and result types are both non-nullable value types. The lifted form is constructed by adding a single ? modifier to the operand and result types. The lifted operator produces a null value if the operand is null. Otherwise, the lifted operator unwraps the operand, applies the underlying operator, and wraps the result.

- For the binary operators
  
  +  -  *  /  %  &  |  ^  <<  >>

  a lifted form of an operator exists if the operand and result types are all non-null value types. The lifted form is constructed by adding a single ? modifier to each operand and result type. The lifted operator produces a null value if one or both operands are null (an exception being the & and | operators of the bool? type, as described in §14.10.4). Otherwise, the lifted operator unwraps the operands, applies the underlying operator, and wraps the result.

- For the equality operators
  
  ==  !=

  a lifted form of an operator exists if the operand types are both non-nullable value types and if the result type is bool. The lifted form is constructed by adding a single ? modifier to each operand type. The lifted operator considers two null values equal, and a null value unequal to any non-null value. If both operands are non-null, the lifted operator unwraps the operands and applies the underlying operator to produce the bool result.

- For the relational operators
  
  <  >  <=  >=
a lifted form of an operator exists if the operand types are both non-nullable value types and if the result type is `bool`. The lifted form is constructed by adding a single `?` modifier to each operand type. The lifted operator produces the value `false` if one or both operands are null. Otherwise, the lifted operator unwraps the operands and applies the underlying operator to produce the `bool` result.

The lifted forms of the predefined operators are themselves considered predefined operators.

### 14.3 Member lookup

A member lookup is the process whereby the meaning of a name in the context of a type is determined. A member lookup can occur as part of evaluating a `simple-name` (§14.5.2) or a `member-access` (§14.5.4) in an expression.

Member lookup considers not only the name of a member but also the number of type parameters the member has and whether the member is accessible. For the purposes of member lookup, generic methods and nested generic types have the number of type parameters indicated in their respective declarations and all other members have zero type parameters.

A member lookup of a name `N` with `K` type parameters in a type `T` is processed as follows:

- First, a set of accessible members named `N` is determined:
  - If `T` is a type parameter, then the set is the union of the sets of accessible members named `N` in each of the types specified as a primary constraint or secondary constraint (§25.7) for `T`, along with the set of accessible members named `N` in `object`.
  - Otherwise, the set consists of all accessible (§10.5) members named `N` in `T`, including inherited members and the accessible members named `N` in `object`. If `T` is a constructed type, the set of members is obtained by substituting type arguments as described in §25.5.4. Members that include an `override` modifier are excluded from the set.

- Next, if the set of accessible members is empty, the member lookup does not produce a match and no further steps are taken.

- Next, if `K` is zero, remove all nested types whose declaration included type parameters. If `K` is not zero, remove all members with a different number of type parameters. Note that when `K` is zero, we do not remove all methods having type parameters, since the type inference process (§25.6.4) might be able to infer the type arguments.

- Next, members that are hidden by other members are removed from the set. Members that are removed during this step may still cause other members to be removed. For every member `S.M` in the set, where `S` is the type in which the member `M` is declared, the following rules are applied:
  - If `M` is a constant, field, property, event, enumeration member, or type declaration then all members declared in a base type of `S` are removed from the set.
  - If `M` is a method, then all non-method members declared in a base type of `S` are removed from the set.

- Next, interface members that are hidden by class members are removed from the set. This step only has an effect if `T` is a type parameter and `T` has both an effective base class other than `object` and a non-empty effective interface set (§25.7). For every member `S.M` in the set, where `S` is the type in which the member `M` is declared, the following rules are applied if `S` is a class declaration other than `object`:
  - If `M` is a constant, field, property, event, enumeration member, or type declaration, then all members declared in an interface declaration are removed from the set.
  - If `M` is a method, then all non-method members declared in an interface declaration are removed from the set.

- Finally, having removed hidden members, the result of the lookup is determined:
If the set consists of a single member that is not a method, then this member is the result of the lookup.

Otherwise, if the set contains only methods, then this group of methods is the result of the lookup.

Otherwise, the lookup is ambiguous, and a compile-time error occurs.

For member lookups in types other than type parameters and interfaces, and member lookups in interfaces that are strictly single-inheritance (each interface in the inheritance chain has exactly zero or one direct base interface), the effect of the lookup rules is simply that derived members hide base members with the same name. Such single-inheritance lookups are never ambiguous. The ambiguities that can possibly arise from member lookups in multiple-inheritance interfaces are described in §20.2.5.

### 14.3.1 Base types

For purposes of member lookup, a type T is considered to have the following base types:

- If T is `object`, then T has no base type.
- If T is an `enum-type`, the base types of T are the class types `System.Enum`, `System.ValueType`, and `object`.
- If T is a `struct-type`, the base types of T are the class types `System.ValueType` and `object`.
- If T is a `class-type`, the base types of T are the base classes of T, including the class type `object`.
- If T is an `interface-type`, the base types of T are the base interfaces of T and the class type `object`.
- If T is an `array-type`, the base types of T are the class types `System.Array` and `object`.
- If T is a `delegate-type`, the base types of T are the class types `System.Delegate` and `object`.
- If T is a `nullable-type`, the base types of T are the class types `System.ValueType` and `object`.

### 14.4 Function members

Function members are members that contain executable statements. Function members are always members of types and cannot be members of namespaces. C# defines the following categories of function members:

- Methods
- Properties
- Events
- Indexers
- User-defined operators
- Instance constructors
- Static constructors
- Finalizers

Except for static constructors and finalizers (which cannot be invoked explicitly), the statements contained in function members are executed through function member invocations. The actual syntax for writing a function member invocation depends on the particular function member category.

The argument list (§14.4.1) of a function member invocation provides actual values or variable references for the parameters of the function member.

Invocations of methods, indexers, operators, and instance constructors employ overload resolution to determine which of a candidate set of function members to invoke. This process is described in §14.4.2.

Once a particular function member has been identified at compile-time, possibly through overload resolution, the actual run-time process of invoking the function member is described in §14.4.3.
Note: The following table summarizes the processing that takes place in constructs involving the six categories of function members that can be explicitly invoked. In the table, \( e, x, y \), and \( \text{value} \) indicate expressions classified as variables or values, \( T \) indicates an expression classified as a type, \( F \) is the simple name of a method, and \( P \) is the simple name of a property.

### 14.4.1 Argument lists

Every function member invocation includes an argument list, which provides actual values or variable references for the parameters of the function member. The syntax for specifying the argument list of a function member invocation depends on the function member category:

- For instance constructors, methods, and delegates, the arguments are specified as an **argument-list**, as described below.
- For properties, the argument list is empty when invoking the **get** accessor, and consists of the expression specified as the right operand of the assignment operator when invoking the **set** accessor.
- For events, the argument list consists of the expression specified as the right operand of the **+=** or **-=** operator.
- For indexers, the argument list consists of the expressions specified between the square brackets in the indexer access. When invoking the **set** accessor, the argument list additionally includes the expression specified as the right operand of the assignment operator. [Note: The additional argument is not used for overload resolution, just during invocation of the set accessor. *end note*]
- For user-defined operators, the argument list consists of the single operand of the unary operator or the two operands of the binary operator.

The arguments of properties (§17.6), events (§17.7), and user-defined operators (§17.9) are always passed as value parameters (§17.5.1.1). The arguments of indexers (§17.8) are always passed as value parameters.
The arguments of an instance constructor, method, or delegate invocation are specified as an argument-list:

```
argument-list:
    argument
    argument-list  ,  argument

argument:
    expression
    ref  variable-reference
    out  variable-reference
```

An argument-list consists of one or more arguments, separated by commas. Each argument can take one of the following forms:

- An expression, indicating that the argument is passed as a value parameter (§17.5.1.1).
- The keyword ref followed by a variable-reference (§12.4), indicating that the argument is passed as a reference parameter (§17.5.1.2). A variable shall be definitely assigned (§12.3) before it can be passed as a reference parameter.
- The keyword out followed by a variable-reference (§12.4), indicating that the argument is passed as an output parameter (§17.5.1.3). A variable is considered definitely assigned (§12.3) following a function member invocation in which the variable is passed as an output parameter.

Passing a volatile field (§17.4.3) as a reference parameter or output parameter causes a warning, since the field may not be treated as volatile by the invoked method.

During the run-time processing of a function member invocation (§14.4.3), the expressions or variable references of an argument list are evaluated in order, from left to right, as follows:

- For a value parameter, the argument expression is evaluated and an implicit conversion (§13.1) to the corresponding parameter type is performed. The resulting value becomes the initial value of the value parameter in the function member invocation.
- For a reference or output parameter, the variable reference is evaluated and the resulting storage location becomes the storage location represented by the parameter in the function member invocation. If the variable reference given as a reference or output parameter is an array element of a reference-type, a run-time check is performed to ensure that the element type of the array is identical to the type of the parameter. If this check fails, a System.ArrayTypeMismatchException is thrown.
- Methods, indexers, and instance constructors can declare their right-most parameter to be a parameter array (§17.5.1.4). Such function members are invoked either in their normal form or in their expanded form depending on which is applicable (§14.4.2.1):
  - When a function member with a parameter array is invoked in its normal form, the argument given for the parameter array shall be a single expression of a type that is implicitly convertible (§13.1) to the parameter array type. In this case, the parameter array acts precisely like a value parameter.
  - When a function member with a parameter array is invoked in its expanded form, the invocation shall specify zero or more arguments for the parameter array, where each argument is an expression of a type that is implicitly convertible (§13.1) to the element type of the parameter array. In this case, the invocation creates an instance of the parameter array type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

The expressions of an argument list are always evaluated in the order they are written. [Example: Thus, the example]
class Test
{
    static void F(int x, int y, int z)
    {
        System.Console.WriteLine("x = {0}, y = {1}, z = {2}", x, y, z);
    }
    static void Main()
    {
        int i = 0;
        F(i++, i++, i++);
    }
}

produces the output
x = 0, y = 1, z = 2

end example

The array covariance rules (§19.5) permit a value of an array type A[] to be a reference to an instance of an array type B[], provided an implicit reference conversion exists from B to A. Because of these rules, when an array element of a reference-type is passed as a reference or output parameter, a run-time check is required to ensure that the actual element type of the array is identical to that of the parameter. [Example: In the following code

class Test
{
    static void F(ref object x) {...}
    static void Main()
    {
        object[] a = new object[10];
        object[] b = new string[10];
        F(ref a[0]); // Ok
        F(ref b[1]); // ArrayTypeMismatchException
    }
}

the second invocation of F causes a System.ArrayTypeMismatchException to be thrown because the actual element type of b is string and not object. end example]

When a function member with a parameter array is invoked in its expanded form, the invocation is processed exactly as if an array creation expression with an array initializer (§14.5.10.2) was inserted around the expanded parameters. [Example: Given the declaration

    void F(int x, int y, params object[] args);

the following invocations of the expanded form of the method

    F(10, 20);
    F(10, 20, 30, 40);
    F(10, 20, 1, "hello", 3.0);

correspond exactly to

    F(10, 20, new object[] {});
    F(10, 20, new object[] {30, 40});
    F(10, 20, new object[] {1, "hello", 3.0});

In particular, note that an empty array is created when there are zero arguments given for the parameter array. end example]

14.4.2 Overload resolution

Overload resolution is a compile-time mechanism for selecting the best function member to invoke given an argument list and a set of candidate function members. Overload resolution selects the function member to invoke in the following distinct contexts within C#:

- Invocation of a method named in an invocation-expression (§14.5.5).
- Invocation of an instance constructor named in an object-creation-expression (§14.5.10.1).
Invocation of an indexer accessor through an element-access (§14.5.6).

Invocation of a predefined or user-defined operator referenced in an expression (§14.2.3 and §14.2.4).

Each of these contexts defines the set of candidate function members and the list of arguments in its own unique way. However, once the candidate function members and the argument list have been identified, the selection of the best function member is the same in all cases:

First, the set of candidate function members is reduced to those function members that are applicable with respect to the given argument list (§14.4.2.1). If this reduced set is empty, a compile-time error occurs.

Then, given the set of applicable candidate function members, the best function member in that set is located. If the set contains only one function member, then that function member is the best function member. Otherwise, the best function member is the one function member that is better than all other function members with respect to the given argument list, provided that each function member is compared to all other function members using the rules in §14.4.2.2. If there is not exactly one function member that is better than all other function members, then the function member invocation is ambiguous and a compile-time error occurs.

The following subclauses define the exact meanings of the terms applicable function member and better function member.

14.4.2.1 Applicable function member

A function member is said to be an applicable function member with respect to an argument list A when all of the following are true:

- The number of arguments in A is identical to the number of parameters in the function member declaration.
- For each argument in A, the parameter passing mode of the argument (i.e., value, ref, or out) is identical to the parameter passing mode of the corresponding parameter, and
  - for a value parameter or a parameter array, an implicit conversion (§13.1) exists from the type of the argument to the type of the corresponding parameter, or
  - for a ref or out parameter, the type of the argument is identical to the type of the corresponding parameter. [Note: After all, a ref or out parameter is an alias for the argument passed. end note]

For a function member that includes a parameter array, if the function member is applicable by the above rules, it is said to be applicable in its normal form. If a function member that includes a parameter array is not applicable in its normal form, the function member might instead be applicable in its expanded form:

- The expanded form is constructed by replacing the parameter array in the function member declaration with zero or more value parameters of the element type of the parameter array such that the number of arguments in the argument list A matches the total number of parameters. If A has fewer arguments than the number of fixed parameters in the function member declaration, the expanded form of the function member cannot be constructed and is thus not applicable.
- Otherwise, the expanded form is applicable if for each argument in A the parameter passing mode of the argument is identical to the parameter passing mode of the corresponding parameter, and
  - for a fixed value parameter or a value parameter created by the expansion, an implicit conversion (§13.1) exists from the type of the argument to the type of the corresponding parameter, or
  - for a ref or out parameter, the type of the argument is identical to the type of the corresponding parameter.
14.4.2.2 Better function member

Given an argument list $A$ with a sequence of argument types $\{A_1, A_2, \ldots, A_n\}$ and two applicable function members $M_P$ and $M_Q$ with parameter types $\{P_1, P_2, \ldots, P_n\}$ and $\{Q_1, Q_2, \ldots, Q_n, M_P\}$, after expansion and type argument substitution, is defined to be a better function member than $M_Q$ if

- for each argument, the implicit conversion from $A_x$ to $P_x$ is not worse than the implicit conversion from $A_x$ to $Q_x$, and
- for at least one argument, the conversion from $A_x$ to $P_x$ is better than the conversion from $A_x$ to $Q_x$.

When performing this evaluation, if $M_P$ or $M_Q$ is applicable only in its expanded form, then $P_x$ or $Q_x$ refers to a parameter in the expanded form of the parameter list.

In case the expanded parameter types $\{P_1, P_2, \ldots, P_n\}$ and $\{Q_1, Q_2, \ldots, Q_n\}$, are identical, the following tie-breaking rules are applied to determine the better function member by comparing the given uninstantiated and unexpanded parameter types $\{R_1, R_2, \ldots, R_k\}$ and $\{S_1, S_2, \ldots, S_l\}$ of the function members $M_P$ and $M_Q$ respectively. In this case, the better function member is determined by the following rules:

- If one of $M_P$ and $M_Q$ is non-generic, but the other is generic, then the non-generic is better.
- Otherwise, if one of $M_P$ and $M_Q$ is applicable in its non-expanded form (or has no params array) and the other is applicable only in its expanded form (and has a params array), then the non-expanded method is better.
- Otherwise, if the numbers of parameters $K$ in $M_P$ and $L$ in $M_Q$ are different, then the method with more parameters is better. Note that this can only occur if both methods have params arrays and are only applicable in their expanded forms.
- Otherwise, the number of parameters $K$ in $M_P$ and $L$ in $M_Q$ are the same, and if one method has more specific parameter types, then that method is better. The given parameter types $\{R_1, R_2, \ldots, R_k\}$ are defined to be more specific than the given parameter types $\{S_1, S_2, \ldots, S_l\}$ if each given parameter $R_x$ is not less specific than $S_x$, and at least one given parameter $R_x$ is more specific than $S_x$. A type parameter is less specific than a non-type parameter. Recursively, a constructed type is more specific than another constructed type (with the same number of type arguments) if at least one type argument is more specific and no type argument is less specific than the corresponding type argument in the other. An array type is more specific than another array type (with the same number of dimensions) if the element type of the first is more specific than the element type of the second.
- Otherwise, if one member is a lifted operator and the other member is an unlifted operator, then the unlifted operator is better.
- Otherwise, neither method is better.

14.4.2.3 Better conversion

Given an implicit conversion $C_1$ that converts from a type $S$ to a type $T_1$, and an implicit conversion $C_2$ that converts from a type $S$ to a type $T_2$, the better conversion of the two conversions is determined as follows:

- If $T_1$ and $T_2$ are the same type, neither conversion is better.
- If $S$ is $T_1$, $C_1$ is the better conversion.
- If $S$ is $T_2$, $C_2$ is the better conversion.
- If an implicit conversion from $T_1$ to $T_2$ exists, and no implicit conversion from $T_2$ to $T_1$ exists, $C_1$ is the better conversion.
- If an implicit conversion from $T_2$ to $T_1$ exists, and no implicit conversion from $T_1$ to $T_2$ exists, $C_2$ is the better conversion.
- If $T_1$ is $sbyte$ and $T_2$ is $byte$, $ushort$, $uint$, or $ulong$, $C_1$ is the better conversion.
- If $T_2$ is $sbyte$ and $T_1$ is $byte$, $ushort$, $uint$, or $ulong$, $C_2$ is the better conversion.
• If \( T_1 \) is \text{short} and \( T_2 \) is \text{ushort}, \text{uint}, or \text{ulong}, \( C_1 \) is the better conversion.
• If \( T_2 \) is \text{short} and \( T_1 \) is \text{ushort}, \text{uint}, or \text{ulong}, \( C_2 \) is the better conversion.
• If \( T_1 \) is \text{int} and \( T_2 \) is \text{ushort}, \text{uint}, or \text{ulong}, \( C_1 \) is the better conversion.
• If \( T_2 \) is \text{int} and \( T_1 \) is \text{ushort}, \text{uint}, or \text{ulong}, \( C_2 \) is the better conversion.
• If \( T_1 \) is \text{long} and \( T_2 \) is \text{ulong}, \( C_1 \) is the better conversion.
• If \( T_2 \) is \text{long} and \( T_1 \) is \text{ulong}, \( C_2 \) is the better conversion.
• Otherwise, neither conversion is better.

If an implicit conversion \( C_1 \) is defined by these rules to be a better conversion than an implicit conversion \( C_2 \), then it is also the case that \( C_2 \) is a \textit{worse conversion} than \( C_1 \).

### 14.4.3 Function member invocation

This subclause describes the process that takes place at run-time to invoke a particular function member. It is assumed that a compile-time process has already determined the particular member to invoke, possibly by applying overload resolution to a set of candidate function members.

For purposes of describing the invocation process, function members are divided into two categories:

- Static function members. These are static methods, static property accessors, and user-defined operators. Static function members are always non-virtual.
- Instance function members. These are instance methods, instance constructors, instance property accessors, and indexer accessors. Instance function members are either non-virtual or virtual, and are always invoked on a particular instance. The instance is computed by an instance expression, and it becomes accessible within the function member as \texttt{this} (§14.5.7). For an instance constructor, the instance expression is taken to be the newly allocated object.

The run-time processing of a function member invocation consists of the following steps, where \( M \) is the function member and, if \( M \) is an instance member, \( E \) is the instance expression:

- If \( M \) is a static function member:
  - The argument list is evaluated as described in §14.4.1.
  - \( M \) is invoked.
- If \( M \) is an instance function member declared in a \textit{value-type}:
  - \( E \) is evaluated. If this evaluation causes an exception, then no further steps are executed. For an instance constructor, this evaluation consists of allocating the storage (typically from an execution stack) for the new object. In this case \( E \) is classified as a variable.
  - If \( E \) is not classified as a variable, then a temporary local variable of \( E \)’s type is created and the value of \( E \) is assigned to that variable. \( E \) is then reclassified as a reference to that temporary local variable. The temporary variable is accessible as \texttt{this} within \( M \), but not in any other way. Thus, only when \( E \) is a true variable is it possible for the caller to observe the changes that \( M \) makes to \texttt{this}.
  - The argument list is evaluated as described in §14.4.1.
  - \( M \) is invoked. The variable referenced by \( E \) becomes the variable referenced by \texttt{this}.
- If \( M \) is an instance function member declared in a \textit{reference-type}:
  - \( E \) is evaluated. If this evaluation causes an exception, then no further steps are executed. For an instance constructor, this evaluation consists of allocating (typically from a garbage-collected heap) the storage for the new object.
  - The argument list is evaluated as described in §14.4.1.
The value of $E$ is checked to be valid: if the type of $E$ is a reference-type, and the value of $E$ is null, a System.NullReferenceException is thrown and no further steps are executed.

The function member implementation to invoke is determined:

- If the compile-time type of $E$ is an interface, the function member to invoke is the implementation of $M$ provided by the run-time type of the instance referenced by $E$. This function member is determined by applying the interface mapping rules (§20.4.2).
- Otherwise, if $M$ is a virtual function member, the function member to invoke is the implementation of $M$ provided by the run-time type of the instance referenced by $E$. This function member is determined by applying the rules for determining the most derived implementation (§17.5.3) of $M$ with respect to the run-time type of the instance referenced by $E$.
- Otherwise, $M$ is a non-virtual function member, and the function member to invoke is $M$ itself.

The function member implementation determined in the step above is invoked. If the type of $E$ is a value-type, then the variable referenced by $E$ becomes the variable referenced by this; otherwise, the type of $E$ is a reference-type and the object referenced by $E$ becomes the object referenced by this.

[Note: If the type of $E$ is a value-type, no boxing occurs even if $M$ is an instance member function declared in a reference-type. end note]

### 14.4.3.1 Invocations on boxed instances

A function member implemented in a value-type can be invoked through a boxed instance of that value-type in the following situations:

- When the function member is an override of a method inherited from type object and is invoked through an instance expression of type object.
- When the function member is an implementation of an interface function member and is invoked through an instance expression of an interface-type.
- When the function member is invoked through a delegate.

In these situations, the boxed instance is considered to contain a variable of the value-type, and this variable becomes the variable referenced by this within the function member invocation. [Note: In particular, this means that when a function member is invoked on a boxed instance, it is possible for the function member to modify the value contained in the boxed instance. end note]

### 14.5 Primary expressions

Primary expressions include the simplest forms of expressions.

\[
\text{primary-expression:}
\begin{align*}
\text{array-creation-expression} \\
\text{primary-no-array-creation-expression}
\end{align*}
\]
primary-no-array-creation-expression:
  literal
  simple-name
  parenthesized-expression
  member-access
  invocation-expression
  element-access
  this-access
  base-access
  post-increment-expression
  post-decrement-expression
  object-creation-expression
  delegate-creation-expression
  typeof-expression
  checked-expression
  unchecked-expression
  default-value-expression
  anonymous-method-expression

Primary expressions are divided between `array-creation-expressions` and `primary-no-array-creation-expressions`. Treating `array-creation-expression` in this way, rather than listing it along with the other simple expression forms, enables the grammar to disallow potentially confusing code such as

```
object o = new int[3][1];
```

which would otherwise be interpreted as

```
object o = (new int[3])[1];
```

A `primary-expression` is permitted to reference a static class (§17.1.1.3) if the `primary-expression` is the $E$ in a `member-access` (§14.5.4) of the form $E.I$.

### 14.5.1 Literals

A `primary-expression` that consists of a `literal` (§9.4.4) is classified as a value.

```
literal::
  boolean-literal
  integer-literal
  real-literal
  character-literal
  string-literal
  null-literal
```

### 14.5.2 Simple names

A `simple-name` consists of an identifier, optionally followed by a type argument list:

```
simple-name:
  identifier  type-argument-list_opt
```

A `simple-name` is either of the form $I$ or of the form $I<A_1, \ldots, A_k>$, where $I$ is a single identifier and $<A_1, \ldots, A_k>$ is an optional `type-argument-list`. When no `type-argument-list` is specified, consider $k$ to be zero. The `simple-name` is evaluated and classified as follows:

- If $k$ is zero and the `simple-name` appears within a `block` and if the `block`’s (or an enclosing `block`’s) local variable declaration space (§10.3) contains a local variable, parameter or constant with name $I$, then the `simple-name` refers to that local variable, parameter or constant and is classified as a variable or value.
- If $k$ is zero and the `simple-name` appears within the body of a generic method declaration and if that declaration includes a type parameter with name $I$, then the `simple-name` refers to that type parameter.
• Otherwise, for each instance type \( T \) (§25.1.2), starting with the instance type of the immediately enclosing type declaration and continuing with the instance type of each enclosing class or struct declaration (if any):
  
  o If \( K \) is zero and the declaration of \( T \) includes a type parameter with name \( I \), then the *simple-name* refers to that type parameter.
  
  o Otherwise, if a member lookup (§14.3) of \( I \) in \( T \) with \( K \) type arguments produces a match:
    
    • If \( T \) is the instance type of the immediately enclosing class or struct type and the lookup identifies one or more methods, the result is a method group with an associated instance expression of `this`. If a type argument list was specified, it is used in calling a generic method (§25.6.3).
    
    • Otherwise, if \( T \) is the instance type of the immediately enclosing class or struct type, if the lookup identifies an instance member, and if the reference occurs within the *block* of an instance constructor, an instance method, or an instance accessor, the result is the same as a member access (§14.5.4) of the form `this.I`. This can only happen when \( K \) is zero.
    
    • Otherwise, the result is the same as a member access (§14.5.4) of the form `T.I` or `T.I<A1, ..., AK>`. In this case, it is a compile-time error for the *simple-name* to refer to an instance member.

• Otherwise, for each namespace \( N \), starting with the namespace in which the *simple-name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
  
  o If \( K \) is zero and \( I \) is the name of a namespace in \( N \), then:
    
    • If the location where the *simple-name* occurs is enclosed by a namespace declaration for \( N \) and the namespace declaration contains an *extern-alias-directive* or *using-alias-directive* that associates the name \( I \) with a namespace or type, then the *simple-name* is ambiguous and a compile-time error occurs.
    
    • Otherwise, the *simple-name* refers to the namespace named \( I \) in \( N \).
  
  o Otherwise, if \( N \) contains an accessible type having name \( I \) and \( K \) type parameters, then:
    
    • If \( K \) is zero and the location where the *simple-name* occurs is enclosed by a namespace declaration for \( N \) and the namespace declaration contains an *extern-alias-directive* or *using-alias-directive* that associates the name \( I \) with a namespace or type, then the *simple-name* is ambiguous and a compile-time error occurs.
    
    • Otherwise, the *namespace-or-type-name* refers to the type constructed with the given type arguments.
  
  o Otherwise, if the location where the *simple-name* occurs is enclosed by a namespace declaration for \( N \):
    
    • If \( K \) is zero and the namespace declaration contains an *extern-alias-directive* or *using-alias-directive* that associates the name \( I \) with an imported namespace or type, then the *simple-name* refers to that namespace or type.
    
    • Otherwise, if the namespaces imported by the *using-namespace-directives* of the namespace declaration contain exactly one type having name \( I \) and \( K \) type parameters, then the *simple-name* refers to that type constructed with the given type arguments.
    
    • Otherwise, if the namespaces imported by the *using-namespace-directives* of the namespace declaration contain more than one type having name \( I \) and \( K \) type parameters, then the *simple-name* is ambiguous and an error occurs.

[Note: This entire step is exactly parallel to the corresponding step in the processing of a *namespace-or-type-name* (§10.8). end note]
• Otherwise, the *simple-name* is undefined and a compile-time error occurs.

14.5.2.1 Invariant meaning in blocks
For each occurrence of a given identifier as a *simple-name* in an expression or declarator, every other occurrence of the same identifier as a *simple-name* in an expression or declarator within the immediately enclosing *block* (§15.2) or *switch-block* (§15.7.2) shall refer to the same entity. [Note: This rule ensures that the meaning of a name is always the same within a block. *end note*]

[Example: The example

```csharp
class Test
{
    double x;
    void F(bool b) {
        x = 1.0;
        if (b) {
            int x = 1;
        }
    }
}
```

results in a compile-time error because *x* refers to different entities within the outer block (the extent of which includes the nested block in the *if* statement). In contrast, the example

```csharp
class Test
{
    double x;
    void F(bool b) {
        if (b) {
            x = 1.0;
        }
        else {
            int x = 1;
        }
    }
}
```

is permitted because the name *x* is never used in the outer block. *end example*]

[Note: The rule of invariant meaning applies only to simple names. It is perfectly valid for the same identifier to have one meaning as a simple name and another meaning as right operand of a member access (§14.5.4). *end note*]

[Example:]

```csharp
struct Point
{
    int x, y;
    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
```

The example above illustrates a common pattern of using the names of fields as parameter names in an instance constructor. In the example, the simple names *x* and *y* refer to the parameters, but that does not prevent the member access expressions *this.*x and *this.*y from accessing the fields. *end example*]

14.5.3 Parenthesized expressions
A *parenthesized-expression* consists of an *expression* enclosed in parentheses.

```
parenthesized-expression:  
(  expression  )
```
A parenthesized-expression is evaluated by evaluating the expression within the parentheses. If the expression within the parentheses denotes a namespace or type, a compile-time error occurs. Otherwise, the result of the parenthesized-expression is the result of the evaluation of the contained expression.

14.5.4 Member access

A member-access consists of a primary-expression, a predefined-type, or a qualified-alias-member, followed by a "." token, followed by an identifier, optionally followed by a type-argument-list.

\[
\text{member-access:} \\
\quad \text{primary-expression} \ . \ \text{identifier type-argument-list}_{\text{opt}} \\
\quad \text{predefined-type} \ . \ \text{identifier type-argument-list}_{\text{opt}} \\
\quad \text{qualified-alias-member} \ . \ \text{identifier type-argument-list}_{\text{opt}}
\]

predefined-type: one of
- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort

qualified-alias-member is defined in §16.7.

A member-access is either of the form \(E.I\) or of the form \(E.I<A_1, \ldots, A_K>\), where \(E\) is a primary-expression, predefined-type or qualified-alias-member, \(I\) is a single identifier and \(<A_1, \ldots, A_K>\) is an optional type-argument-list. When no type-argument-list is specified, consider \(K\) to be zero. The member-access is evaluated and classified as follows:

- If \(K\) is zero and \(E\) is a namespace and \(E\) contains a nested namespace with name \(I\), then the result is that namespace.
- Otherwise, if \(E\) is a namespace and \(E\) contains an accessible type having name \(I\) and \(K\) type parameters, then the result is that type constructed with the given type arguments.
- If \(E\) is a classified as a type, if \(E\) is not a type parameter, and if a member lookup (§14.3) of \(I\) in \(E\) with \(K\) type parameters produces a match, then \(E.I\) is evaluated and classified as follows: [Note: When the result of such a member lookup is a method group and \(K\) is zero, the method group can contain methods having type parameters. This allows such methods to be considered for type argument inferencing. end note]
  - If \(I\) identifies a type, then the result is that type constructed with the given type and any inferred arguments.
  - If \(I\) identifies one or more methods, then the result is a method group with no associated instance expression.
  - If \(I\) identifies a static property, then the result is a property access with no associated instance expression.
  - If \(I\) identifies a static field:
    - If the field is readonly and the reference occurs outside the static constructor of the class or struct in which the field is declared, then the result is a value, namely the value of the static field \(I\) in \(E\).
    - Otherwise, the result is a variable, namely the static field \(I\) in \(E\).
  - If \(I\) identifies a static event:
    - If the reference occurs within the class or struct in which the event is declared, and the event was declared without event-accessor-declarations (§17.7), then \(E.I\) is processed exactly as if \(I\) were a static field.
    - Otherwise, the result is an event access with no associated instance expression.
  - If \(I\) identifies a constant, then the result is a value, namely the value of that constant.
If \( I \) identifies an enumeration member, then the result is a value, namely the value of that
enumeration member.

Otherwise, \( E.I \) is an invalid member reference, and a compile-time error occurs.

- If \( E \) is a property access, indexer access, variable, or value, the type of which is \( T \), and a member lookup
\((\S 14.3)\) of \( I \) in \( T \) with \( K \) type arguments produces a match, then \( E.I \) is evaluated and classified as
follows:
  - First, if \( E \) is a property or indexer access, then the value of the property or indexer access is obtained
\((\S 14.1.1)\) and \( E \) is reclassified as a value.
  - If \( I \) identifies one or more methods, then the result is a method group with an associated instance
expression of \( E \). If a type argument list was specified, the method group consists only of generic
methods having \( K \) type parameters and the type argument list is implicitly applied to each method in
the method group \((\S 25.6.3)\). If no type argument list was specified, the method group may contain
both generic and non-generic methods.
  - If \( I \) identifies an instance property, then the result is a property access with an associated instance
expression of \( E \).
  - If \( T \) is a class-type and \( I \) identifies an instance field of that class-type:
    - If the value of \( E \) is \( \text{null} \), then a \text{System.NullReferenceException} is thrown.
    - Otherwise, if the field is \text{readonly} and the reference occurs outside an instance constructor of
the class in which the field is declared, then the result is a value, namely the value of the field \( I \)
in the object referenced by \( E \).
    - Otherwise, the result is a variable, namely the field \( I \) in the object referenced by \( E \).
  - If \( T \) is a struct-type and \( I \) identifies an instance field of that struct-type:
    - If \( E \) is a value, or if the field is \text{readonly} and the reference occurs outside an instance
constructor of the struct in which the field is declared, then the result is a value, namely the
value of the field \( I \) in the struct instance given by \( E \).
    - Otherwise, the result is a variable, namely the field \( I \) in the struct instance given by \( E \).
  - If \( I \) identifies an instance event:
    - If the reference occurs within the class or struct in which the event is declared, and the event
was declared without \text{event-accessor-declarations} \((\S 17.7)\), then \( E.I \) is processed exactly as if \( I \)
was an instance field.
    - Otherwise, the result is an event access with an associated instance expression of \( E \).
- Otherwise, \( E.I \) is an invalid member reference, and a compile-time error occurs.

### 14.5.4.1 Identical simple names and type names

In a member access of the form \( E.I \), if \( E \) is a single identifier, and if the meaning of \( E \) as a \text{simple-name}
\((\S 14.5.2)\) is a constant, field, property, local variable, or parameter with the same type as the meaning of \( E \) as
a \text{type-name} \((\S 10.8)\), then both possible meanings of \( E \) are permitted. The two possible meanings of \( E.I \) are
never ambiguous, since \( I \) shall necessarily be a member of the type \( E \) in both cases. In other words, the rule
simply permits access to the static members and nested types of \( E \) where a compile-time error would
otherwise have occurred. [Example:

```csharp
struct Color
{
    public static readonly Color White = new Color(...);
    public static readonly Color Black = new Color(...);
    public Color Complement() { ... }
}
```
14.5.5 Invocation expressions

An invocation-expression is used to invoke a method.

\[
\text{invocation-expression:} \quad \text{primary-expression} \ (\ \text{argument-list}_{\text{opt}} \ )
\]

The primary-expression of an invocation-expression shall be a method group or a value of a delegate-type. If the primary-expression is a method group, the invocation-expression is a method invocation (§14.5.5.1). If the primary-expression is a value of a delegate-type, the invocation-expression is a delegate invocation (§14.5.5.2). If the primary-expression is neither a method group nor a value of a delegate-type, a compile-time error occurs.

The optional argument-list (§14.4.1) provides values or variable references for the parameters of the method. The result of evaluating an invocation-expression is classified as follows:

- If the invocation-expression invokes a method or delegate that returns void, the result is nothing. An expression that is classified as nothing cannot be an operand of any operator, and is permitted only in the context of a statement-expression (§15.6).
- Otherwise, the result is a value of the type returned by the method or delegate.

14.5.5.1 Method invocations

For a method invocation, the primary-expression of the invocation-expression shall be a method group. The method group identifies the one method to invoke or the set of overloaded methods from which to choose a specific method to invoke. In the latter case, determination of the specific method to invoke is based on the context provided by the types of the arguments in the argument-list.

The compile-time processing of a method invocation of the form M(A), where M is a method group (possibly including a type-argument-list), and A is an optional argument-list, consists of the following steps:

- The set of candidate methods for the method invocation is constructed. For each method F associated with the method group M:
  - If F is non-generic, F is a candidate when:
    - M has no type argument list, and
    - F is applicable with respect to A (§14.4.2.1).
  - If F is generic and M has no type argument list, F is a candidate when:
    - Type inference (§25.6.4) succeeds, inferring a list of type arguments for the call, and
    - Once the inferred type arguments are substituted for the corresponding method type parameters, the parameter list of F is applicable with respect to A (§14.4.2.1), and
  - If F is generic and M includes a type argument list, F is a candidate when:
• F has the same number of method type parameters as were supplied in the type argument list, and
• Once the type arguments are substituted for the corresponding method type parameters, the parameter list of F is applicable with respect to A (§14.4.2.1).
• The set of candidate methods is reduced to contain only methods from the most derived types: For each method C.F in the set, where C is the type in which the method F is declared, all methods declared in a base type of C are removed from the set. Furthermore, if C is a class type other than object, all methods declared in an interface type are removed from the set. [Note: This latter rule only has affect when the method group was the result of a member lookup on a type parameter having an effective base class other than object and a non-empty effective interface set (§25.7). end note]
• If the resulting set of candidate methods is empty, then no applicable methods exist, and a compile-time error occurs.
• The best method of the set of candidate methods is identified using the overload resolution rules of §14.4.2. If a single best method cannot be identified, the method invocation is ambiguous, and a compile-time error occurs. When performing overload resolution, the parameters of a generic method are considered after substituting the type arguments (supplied or inferred) for the corresponding method type parameters.
• Final validation of the chosen best method is performed:
  o The method is validated in the context of the method group: If the best method is a static method, the method group shall have resulted from a simple-name or a member-access through a type. If the best method is an instance method, the method group shall have resulted from a simple-name, a member-access through a variable or value, or a base-access. If neither of these requirements is true, a compile-time error occurs.
  o If the best method is a generic method, the type arguments (supplied or inferred) are checked against the constraints (§25.7.1) declared on the generic method. If any type argument does not satisfy the corresponding constraint(s) on the type parameter, a compile-time error occurs.

Once a method has been selected and validated at compile-time by the above steps, the actual run-time invocation is processed according to the rules of function member invocation described in §14.4.3.

[Note: The intuitive effect of the resolution rules described above is as follows: To locate the particular method invoked by a method invocation, start with the type indicated by the method invocation and proceed up the inheritance chain until at least one applicable, accessible, non-override method declaration is found. Then perform overload resolution on the set of applicable, accessible, non-override methods declared in that type and invoke the method thus selected. end note]

14.5.5.2 Delegate invocations

For a delegate invocation, the primary-expression of the invocation-expression shall be a value of a delegate-type. Furthermore, considering the delegate-type to be a function member with the same parameter list as the delegate-type, the delegate-type shall be applicable (§14.4.2.1) with respect to the argument-list of the invocation-expression.

The run-time processing of a delegate invocation of the form D(A), where D is a primary-expression of a delegate-type and A is an optional argument-list, consists of the following steps:

• D is evaluated. If this evaluation causes an exception, no further steps are executed.
• The argument list A is evaluated. If this evaluation causes an exception, no further steps are executed.
• The value of D is checked to be valid. If the value of D is null, a System.NullReferenceException is thrown and no further steps are executed.
• Otherwise, D is a reference to a delegate instance. A function member invocation (§14.4.3) is performed on each callable entity referenced by the delegate. If invocation of a callable entity causes an exception,
the remaining callable entities are not invoked. Otherwise, the return result of the invocation is the result returned from the last callable entity.

### 14.5.6 Element access

An element-access consists of a primary-no-array-creation-expression, followed by a “[” token, followed by an expression-list, followed by a “]” token. The expression-list consists of one or more expressions, separated by commas.

```
  element-access:
    primary-no-array-creation-expression  [  expression-list  ]
```

expression-list:

```
  expression
  expression-list  ,  expression
```

If the primary-no-array-creation-expression of an element-access is a value of an array-type, the element-access is an array access (§14.5.6.1). Otherwise, the primary-no-array-creation-expression shall be a variable or value of a class, struct, or interface type that has one or more indexer members, in which case the element-access is an indexer access (§14.5.6.2).

#### 14.5.6.1 Array access

For an array access, the primary-no-array-creation-expression of the element-access shall be a value of an array-type. The number of expressions in the expression-list shall be the same as the rank of the array-type, and each expression shall be of type int, uint, long, ulong, or of a type that can be implicitly converted to one or more of these types.

The result of evaluating an array access is a variable of the element type of the array, namely the array element selected by the value(s) of the expression(s) in the expression-list.

The run-time processing of an array access of the form P[A], where P is a primary-no-array-creation-expression of an array-type and A is an expression-list, consists of the following steps:

- P is evaluated. If this evaluation causes an exception, no further steps are executed.
- The index expressions of the expression-list are evaluated in order, from left to right. Following evaluation of each index expression, an implicit conversion (§13.1) to one of the following types is performed: int, uint, long, ulong. The first type in this list for which an implicit conversion exists is chosen. For instance, if the index expression is of type short then an implicit conversion to int is performed, since implicit conversions from short to int and from short to long are possible. If evaluation of an index expression or the subsequent implicit conversion causes an exception, then no further index expressions are evaluated and no further steps are executed.
- The value of P is checked to be valid. If the value of P is null, a System.NullReferenceException is thrown and no further steps are executed.
- The value of each expression in the expression-list is checked against the actual bounds of each dimension of the array instance referenced by P. If one or more values are out of range, a System.IndexOutOfRangeException is thrown and no further steps are executed.
- The location of the array element given by the index expression(s) is computed, and this location becomes the result of the array access.

#### 14.5.6.2 Indexer access

For an indexer access, the primary-no-array-creation-expression of the element-access shall be a variable or value of a class, struct, or interface type, and this type shall implement one or more indexers that are applicable with respect to the expression-list of the element-access.
The compile-time processing of an indexer access of the form \( P[A] \), where \( P \) is a primary-no-array-creation-expression of a class, struct, or interface type \( T \), and \( A \) is an expression-list, consists of the following steps:

- The set of indexers provided by \( T \) is constructed. The set consists of all indexers declared in \( T \) or a base type of \( T \) that are not override declarations and are accessible in the current context (§10.5).
- The set is reduced to those indexers that are applicable and not hidden by other indexers. The following rules are applied to each indexer \( S.I \) in the set, where \( S \) is the type in which the indexer \( I \) is declared:
  - If \( I \) is not applicable with respect to \( A \) (§14.4.2.1), then \( I \) is removed from the set.
  - If \( I \) is applicable with respect to \( A \) (§14.4.2.1), then all indexers declared in a base type of \( S \) are removed from the set.
- If the resulting set of candidate indexers is empty, then no applicable indexers exist, and a compile-time error occurs. If the candidate indexers are not all declared in the same type, the indexer access is ambiguous, and a compile-time error occurs (this latter situation can only occur for an indexer access on an instance of an interface that has multiple direct base interfaces, or for an invocation of an indexer on a type parameter).
- The best indexer of the set of candidate indexers is identified using the overload resolution rules of §14.4.2. If a single best indexer cannot be identified, the indexer access is ambiguous, and a compile-time error occurs.
- The index expressions of the expression-list are evaluated in order, from left to right. The result of processing the indexer access is an expression classified as an indexer access. The indexer access expression references the indexer determined in the step above, and has an associated instance expression of \( P \) and an associated argument list of \( A \).

Depending on the context in which it is used, an indexer access causes invocation of either the get-accessor or the set-accessor of the indexer. If the indexer access is the target of an assignment, the set-accessor is invoked to assign a new value (§14.14.1). In all other cases, the get-accessor is invoked to obtain the current value (§14.1.1).

### 14.5.7 This access

A this-access consists of the reserved word this.

```
this-access:
  this
```

A this-access is permitted only in the block of an instance constructor, an instance method, or an instance accessor. It has one of the following meanings:

- When \texttt{this} is used in a primary-expression within an instance constructor of a class, it is classified as a value. The type of the value is the class within which the usage occurs, and the value is a reference to the object being constructed.
- When \texttt{this} is used in a primary-expression within an instance method or instance accessor of a class, it is classified as a value. The type of the value is the class within which the usage occurs, and the value is a reference to the object for which the method or accessor was invoked.
- When \texttt{this} is used in a primary-expression within an instance constructor of a struct, it is classified as a variable. The type of the variable is the struct within which the usage occurs, and the variable represents the struct being constructed. The \texttt{this} variable of an instance constructor of a struct behaves exactly the same as:
  - an out parameter of the struct type if the constructor declaration has no constructor initializer. In particular, this means that the variable shall be definitely assigned in every execution path of the instance constructor.
• a `ref` parameter of the struct type if the constructor declaration has a constructor initializer. In particular, this means that the variable is considered initially assigned.

- When `this` is used in a `primary-expression` within an instance method or instance accessor of a struct, it is classified as a variable. The type of the variable is the struct within which the usage occurs, and the variable represents the struct for which the method or accessor was invoked. The `this` variable of an instance method of a struct behaves exactly the same as a `ref` parameter of the struct type.

Use of `this` in a `primary-expression` in a context other than the ones listed above is a compile-time error. In particular, it is not possible to refer to `this` in a static method, a static property accessor, or in a `variable-initializer` of a field declaration.

### 14.5.8 Base access

A `base-access` consists of the reserved word `base` followed by either a “.” token and an identifier and optional `type-argument-list` or an `expression-list` enclosed in square brackets:

```
base-access:
  base . identifier type-argument-listopt
  base [ expression-list ]
```

A `base-access` is used to access base class members that are hidden by similarly named members in the current class or struct. A `base-access` is permitted only in the `block` of an instance constructor, an instance method, or an instance accessor. When `base.I` occurs in a class or struct, `I` shall denote a member of the base class of that class or struct. Likewise, when `base[E]` occurs in a class, an applicable indexer shall exist in the base class.

At compile-time, `base-access` expressions of the form `base.I` and `base[E]` are evaluated exactly as if they were written `((B)this).I` and `((B)this)[E]`, where `B` is the base class of the class or struct in which the construct occurs. Thus, `base.I` and `base[E]` correspond to `this.I` and `this[E]`, except `this` is viewed as an instance of the base class.

When a `base-access` references a virtual function member (a method, property, or indexer), the determination of which function member to invoke at run-time (§14.4.3) is changed. The function member that is invoked is determined by finding the most derived implementation (§17.5.3) of the function member with respect to `B` (instead of with respect to the run-time type of `this`, as would be usual in a non-base access). Thus, within an `override` of a virtual function member, a `base-access` can be used to invoke the inherited implementation of the function member. If the function member referenced by a `base-access` is abstract, a compile-time error occurs.

### 14.5.9 Postfix increment and decrement operators

```
post-increment-expression:
  primary-expression ++

post-decrement-expression:
  primary-expression --
```

The operand of a postfix increment or decrement operation shall be an expression classified as a variable, a property access, or an indexer access. The result of the operation is a value of the same type as the operand. If the operand of a postfix increment or decrement operation is a property or indexer access, the property or indexer shall have both a `get` and a `set` accessor. If this is not the case, a compile-time error occurs.

Unary operator overload resolution (§14.2.3) is applied to select a specific operator implementation. Predefined `++` and `--` operators exist for the following operand types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type. The result type of each of these predefined operators is the same as the operand type. The predefined `++` operators return the value produced by adding 1 to the operand, and the predefined `--` operators return the value produced by subtracting 1 from the operand. In a `checked` context, if the result of this addition or subtraction is outside the range of the result type, a `System.OverflowException` is thrown.
C# LANGUAGE SPECIFICATION

There shall be an implicit conversion from the return type of the selected unary operator to the type of the primary-expression, otherwise a compile-time error occurs.

The run-time processing of a postfix increment or decrement operation of the form x++ or x-- consists of the following steps:

- If x is classified as a variable:
  - x is evaluated to produce the variable.
  - The value of x is saved.
  - The saved value of x is converted to the operand type of the selected operator and the operator is invoked with this value as its argument.
  - The value returned by the operator is converted to the type of x and stored in the location given by the evaluation of x.
  - The saved value of x becomes the result of the operation.

- If x is classified as a property or indexer access:
  - The instance expression (if x is not static) and the argument list (if x is an indexer access) associated with x are evaluated, and the results are used in the subsequent get and set accessor invocations.
  - The get accessor of x is invoked and the returned value is saved.
  - The saved value of x is converted to the operand type of the selected operator and the operator is invoked with this value as its argument.
  - The value returned by the operator is converted to the type of x and the set accessor of x is invoked with this value as its value argument.
  - The saved value of x becomes the result of the operation.

The ++ and -- operators also support prefix notation (§14.6.5). The result of x++ or x-- is the value of x before the operation, whereas the result of ++x or --x is the value of x after the operation. In either case, x itself has the same value after the operation.

An operator ++ or operator -- implementation can be invoked using either postfix or prefix notation. It is not possible to have separate operator implementations for the two notations.

Lifted (§14.2.7) forms of the unlifted predefined postfix increment and decrement operators defined above are also predefined.

14.5.10 The new operator

The new operator is used to create new instances of types.

There are three forms of new expressions:

- Object creation expressions are used to create new instances of class types and value types.
- Array creation expressions are used to create new instances of array types.
- Delegate creation expressions are used to create new instances of delegate types.

The new operator implies creation of an instance of a type, but does not necessarily imply dynamic allocation of memory. In particular, instances of value types require no additional memory beyond the variables in which they reside, and no dynamic allocations occur when new is used to create instances of value types.

14.5.10.1 Object creation expressions

An object-creation-expression is used to create a new instance of a class-type or a value-type.
object-creation-expression:
\[
\text{new type ( } \text{argument-list}_{opt} \text{ )}
\]
The type of an object-creation-expression shall be a class-type, a value-type, or a type-parameter having the constructor-constraint or the value type constraint (§25.7). The type cannot be an abstract class-type.

The optional argument-list (§14.4.1) is permitted only if the type is a class-type or a struct-type, and not a type-parameter.

The compile-time processing of an object-creation-expression of the form \texttt{new T(A)}, where T is a class-type, a value-type, or a type-parameter, and A is an optional argument-list, consists of the following steps:

- If T is a value-type and A is not present:
  - The object-creation-expression is a default constructor invocation. The result of the object-creation-expression is a value of type T, namely the default value for T as defined in §11.1.2.
- Otherwise, if T is a class-type or a struct-type:
  - If T is an abstract class-type, a compile-time error occurs.
  - The instance constructor to invoke is determined using the overload resolution rules of §14.4.2. The set of candidate instance constructors consists of all accessible instance constructors declared in T. If the set of candidate instance constructors is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs.
  - The result of the object-creation-expression is a value of type T, namely the value produced by invoking the instance constructor determined in the step above.
- Otherwise, if T is a type-parameter:
  - If A is present, a compile-time error occurs.
  - Otherwise, if T has the constructor-constraint or the value type constraint, the result of the object-creation-expression is a value of type T.
  - Otherwise, the object-creation-expression is invalid, and a compile-time error occurs.
- Otherwise, the object-creation-expression is invalid, and a compile-time error occurs.

The run-time processing of an object-creation-expression of the form \texttt{new T(A)}, where T is class-type, a struct-type, or a type-parameter, and A is an optional argument-list, consists of the following steps:

- If T is a class-type:
  - A new instance of class T is allocated. If there is not enough memory available to allocate the new instance, a System.OutOfMemoryException is thrown and no further steps are executed.
  - All fields of the new instance are initialized to their default values (§12.2).
  - The instance constructor is invoked according to the rules of function member invocation (§14.4.3). A reference to the newly allocated instance is automatically passed to the instance constructor and the instance can be accessed from within that constructor as \texttt{this}.
- If T is a struct-type:
  - An instance of type T is created by allocating a temporary local variable. Since an instance constructor of a struct-type is required to definitely assign a value to each field of the instance being created, no initialization of the temporary variable is necessary.
  - The instance constructor is invoked according to the rules of function member invocation (§14.4.3). A reference to the newly allocated instance is automatically passed to the instance constructor and the instance can be accessed from within that constructor as \texttt{this}.
- If T is a type-parameter:
If \( T \) evaluates at run-time to a value type, the result is the default value of this type (§11.1.2). This is always the case if \( T \) has the value type constraint.

Otherwise, \( T \) shall evaluate at run-time to a non-abstract class type having a public constructor taking no parameters. The result is a new instance of this class type:

- A new instance of the class is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
- All fields of the new instance are initialized to their default values (§12.2).
- The instance constructor is invoked according to the rules of function member invocation (§14.4.3). A reference to the newly allocated instance is automatically passed to the instance constructor and the instance can be accessed from within that constructor as `this`.

Note: The run-time type need not be accessible to the code containing the object-creation-expression. Nevertheless, the run-time environment shall support invoking the constructor. end note

14.5.10.2 Array creation expressions

An `array-creation-expression` is used to create a new instance of an `array-type`.

```
array-creation-expression:
  new non-array-type [ expression-list ] rank-specifiersopt array-initializeropt
  new array-type array-initializer
```

An array creation expression of the first form allocates an array instance of the type that results from deleting each of the individual expressions from the expression list. [Example: The array creation expression `new int[10, 20]` produces an array instance of type `int[,]`, and the array creation expression `new int[10][,]` produces an array of type `int[][]`. end example] Each expression in the expression list shall be of type `int`, `uint`, `long`, or `ulong`, or of a type that can be implicitly converted to one or more of these types. The value of each expression determines the length of the corresponding dimension in the newly allocated array instance. Since the length of an array dimension shall be nonnegative, it is a compile-time error to have a constant expression with a negative value, in the expression list.

Except in an unsafe context (§27.1), the layout of arrays is unspecified.

If an array creation expression of the first form includes an array initializer, each expression in the expression list shall be a constant expression (§14.16) and the rank and dimension lengths specified by the expression list shall match those of the array initializer.

In an array creation expression of the second form, the rank of the specified array type shall match that of the array initializer. The individual dimension lengths are inferred from the number of elements in each of the corresponding nesting levels of the array initializer. Thus, the expression

```
new int[,] {{{0, 1}, {2, 3}, {4, 5}}
```

exactly corresponds to

```
new int[3, 2] {{0, 1}, {2, 3}, {4, 5}}
```

Array initializers are described further in §19.7.

The result of evaluating an array creation expression is classified as a value, namely a reference to the newly allocated array instance. The run-time processing of an array creation expression consists of the following steps:

- The dimension length expressions of the `expression-list` are evaluated in order, from left to right.
  Following evaluation of each expression, an implicit conversion (§13.1) to one of the following types is performed: `int`, `uint`, `long`, `ulong`. The first type in this list for which an implicit conversion exists is chosen. If evaluation of an expression or the subsequent implicit conversion causes an exception, then no further expressions are evaluated and no further steps are executed.
• The computed values for the dimension lengths are validated, as follows: If one or more of the values are less than zero, a `System.OverflowException` is thrown and no further steps are executed.
• An array instance with the given dimension lengths is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
• All elements of the new array instance are initialized to their default values (§12.2).
• If the array creation expression contains an array initializer, then each expression in the array initializer is evaluated and assigned to its corresponding array element. The evaluations and assignments are performed in the order the expressions are written in the array initializer—in other words, elements are initialized in increasing index order, with the rightmost dimension increasing first. If evaluation of a given expression or the subsequent assignment to the corresponding array element causes an exception, then no further elements are initialized (and the remaining elements will thus have their default values).

An array creation expression permits instantiation of an array with elements of an array type, but the elements of such an array shall be manually initialized. [Example: The statement

```csharp
int[,] a = new int[100][];
```

creates a single-dimensional array with 100 elements of type `int[]`. The initial value of each element is `null`. It is not possible for the same array creation expression to also instantiate the sub-arrays (without an array initializer), and the statement

```csharp
int[,] a = new int[100][5];  // Error
```

results in a compile-time error. Instantiation of the sub-arrays can instead be performed manually or using an array initializer, as in

```csharp
int[,] a = new int[100][];
for (int i = 0; i < 100; i++) a[i] = new int[5];
int[,] b = new int[3][] { new int[1], new int[2], new int[3] };
```

[Note: When an array of arrays has a “rectangular” shape, that is when the sub-arrays are all of the same length, it is more efficient to use a multi-dimensional array. In the example above, instantiation of the array of arrays creates 101 objects—one outer array and 100 sub-arrays. In contrast,

```csharp
int[,] = new int[100, 5];
```

creates only a single object, a two-dimensional array, and accomplishes the allocation in a single statement. end note]

14.5.10.3 Delegate creation expressions

A `delegate-creation-expression` is used to create a new instance of a `delegate-type`.

`delegate-creation-expression`:

```
new delegate-type ( expression )
```

The argument of a delegate creation expression shall be a method group (§14.1), an `anonymous-method-expression` (§14.5.15), or a value of a `delegate-type`. If the argument is a method group, it identifies the method, type arguments (for a generic method) and, for an instance method, the object for which to create a delegate. If the argument is a value of a `delegate-type`, it identifies a delegate instance of which to create a copy.

If the `expression` is an `anonymous-method-expression` (§14.5.15), then the anonymous method is converted to the given delegate type using the implicit conversion rules defined in §13.5. [Example: If `D` is a delegate type, then the expression

```csharp
new D(delegate { Console.WriteLine("hello"); })
```

is equivalent to the expression
(D) delegate { Console.WriteLine("hello"); }  
end example]

The compile-time processing of a delegate-creation-expression of the form `new D(E)`, where `D` is a delegate-type and `E` is an expression, consists of the following steps:

- If `E` is a method group:
  - A single method is selected corresponding to a method invocation (§14.5.5.1) of the form `E(A)`, with the following modifications:
    - The parameter types and modifiers (ref or out) of `D` are used as the argument types and modifiers of the argument list `A`.
    - The candidate methods considered are only those methods that are applicable in their normal form (§14.4.2.1), not those applicable only in their expanded form.
    - If the algorithm of §14.5.5.1 produces an error, then a compile-time error occurs. Otherwise the algorithm produces a single best method `M`, together with its type arguments (if the method is generic), having the same number of parameters as `D`.
      - If the selected `M` is not consistent (§22.1) with the delegate type `D`, a compiler-time error occurs.
      - If the method `M` is an instance method, the instance expression associated with `E` determines the target object of the delegate.
      - The result is a value of type `D`, namely a newly created delegate that refers to the method `M` and target object.
  - Otherwise, if `E` is a value of a delegate-type:
    - If `D` and `E` have different numbers of parameters, a compile-time error occurs.
    - If there is not an identity conversion or implicit reference conversion from the return type of `E` to the return type of `D`, a compile-time error occurs.
    - If for some parameter of `D` there is not an identity conversion or implicit reference conversion from the parameter type to the corresponding parameter type of `E`, a compile-time error occurs.
    - If any parameter of `D` or `E` has a parameter modifier (ref or out), then the other corresponding parameter must have the same modifier and the same type.
    - The result is a value of type `D`, namely a newly created delegate that refers to the same invocation list as `E`.
  - Otherwise, the delegate creation expression is invalid, and a compile-time error occurs.

The run-time processing of a delegate-creation-expression of the form `new D(E)`, where `D` is a delegate-type and `E` is an expression, consists of the following steps:

- If `E` is a method group:
  - If the method selected at compile-time is a static method, the target object of the delegate is `null`. Otherwise, the selected method is an instance method, and the target object of the delegate is determined from the instance expression associated with `E`:
    - The instance expression is evaluated. If this evaluation causes an exception, no further steps are executed.
    - If the instance expression is of a reference-type, the value computed by the instance expression becomes the target object. If the target object is `null`, a System.NullReferenceException is thrown and no further steps are executed.
    - If the instance expression is of a value-type, a boxing operation (§11.3.1) is performed to convert the value to an object, and this object becomes the target object.
A new instance of the delegate type D is allocated. If there is not enough memory available to allocate the new instance, a System.OutOfMemoryException is thrown and no further steps are executed.

The new delegate instance is initialized with a reference to the method that was determined at compile-time and a reference to the target object computed above.

- If E is a value of a delegate-type:
  - E is evaluated. If this evaluation causes an exception, no further steps are executed.
  - If the value of E is null, a System.NullReferenceException is thrown and no further steps are executed.
  - A new instance of the delegate type D is allocated. If there is not enough memory available to allocate the new instance, a System.OutOfMemoryException is thrown and no further steps are executed.
  - The new delegate instance is initialized with references to the same invocation list as the delegate instance given by E.

The method and object to which a delegate refers are determined when the delegate is instantiated and then remain constant for the entire lifetime of the delegate. In other words, it is not possible to change the target method or object of a delegate once it has been created. [Note: Remember, when two delegates are combined or one is removed from another, a new delegate results; no existing delegate has its content changed. end note]

It is not possible to create a delegate that refers to a property, indexer, user-defined operator, instance constructor, finalizer, or static constructor.

[Example: As described above, when a delegate is created from a method group, the formal parameter list and return type of the delegate determine which of the overloaded methods to select. In the example

```csharp
delegate double DoubleFunc(double x);
class A
{
    DoubleFunc f = new DoubleFunc(Square);
    static float Square(float x) {
        return x * x;
    }
    static double Square(double x) {
        return x * x;
    }
}
```

the A.f field is initialized with a delegate that refers to the second Square method because overload resolution with an argument list consisting of a lone double value would choose that method. Had the second Square method not been present, a compile-time error would have occurred.

The definition of a method being consistent with a delegate type (§22.1) permits covariance in the return type and contra-variance in the parameter types. That is, the method return type may be more specific than the delegate return type and the method parameter types may be less specific than the delegate parameter types. In the example

```csharp
delegate object StrToObj(string s);
class A
{
    StrToObj f = new StrToObj(ObjToStr);
    static string ObjToStr(object x) {
        return x.ToString();
    }
}
```
the method ObjToStr is used to create a delegate of type StrToObj. The method is consistent with the
delegate type since there is an implicit reference conversion from the parameter type of the delegate to the
parameter type of the method and an implicit reference conversion from the return type of the method to the
return type of the delegate.

Here's another variance-related example:

default void D1(int i);
default void D2(long l);
class Program
{
    static void M(long l) { }
    static void F(D1 d) {}
    static void F(D2 d) {}
    static void Main() {
        D1 d1 = new D1(M);
        // Error: M is compatible with D1,
        // but inconsistent, because the conversion from
        // int to long is not an implicit reference
        // conversion.
        F(M); // Error: ambiguity between F(D1) and F(D2). M is
        // compatible with both D1 and D2. However M is
        // consistent with D2, while inconsistent with D1.
    }
}
end example]

14.5.11 The typeof operator

The typeof operator is used to obtain the System.Type object for a type.

typeof-expression:
    typeof ( type )
    typeof ( unbound-type-name )
    typeof ( void )

unbound-type-name:
    identifier generic-dimension-specifier_opt
    identifier :: identifier generic-dimension-specifier_opt
    unbound-type-name . identifier generic-dimension-specifier_opt

generic-dimension-specifier:
    < commas_opt >

commas:
    ,
    commas

The first form of typeof-expression consists of a typeof keyword followed by a parenthesized type. The
result of an expression of this form is the System.Type object for the indicated type. There is only one
System.Type object for any given type. [Note: This means that for type T, typeof(T) == typeof(T)
is always true. end note]

The second form of typeof-expression consists of a typeof keyword followed by a parenthesized unbound-
type-name. [Note: An unbound-type-name is very similar to a type-name (§10.8) except that an unbound-
type-name contains generic-dimension-specifiers where a type-name contains type-argument-lists. end note] When the operand of a typeof-expression is a sequence of tokens that satisfies the grammars of both
unbound-type-name and type-name, namely when it contains neither a generic-dimension-specifier nor a
type-argument-list, the sequence of tokens is considered to be a type-name. The meaning of an unbound-
type-name is determined as follows:
14 Expressions

- Convert the sequence of tokens to a type-name by replacing each generic-dimension-specifier with a type-argument-list having the same number of commas and the keyword object as each type-argument.
- Evaluate the resulting type-name, while ignoring all type parameter constraints.
- The unbound-type-name resolves to the unbound generic type associated with the resulting constructed type (§25.5).

The result of the typeof-expression is the System.Type object for the resulting unbound generic type.

The third form of typeof-expression consists of a typeof keyword followed by a parenthesized void keyword. The result of an expression of this form is the System.Type object that represents the absence of a type. The type object returned by typeof(void) is distinct from the type object returned for any type. [Note: This special type object is useful in class libraries that allow reflection onto methods in the language, where those methods wish to have a way to represent the return type of any method, including void methods, with an instance of System.Type. end note]

[Example: The example
using System;
class Test
{
    static void Main()
    {
        Type[] t = {
            typeof(int),
            typeof(System.Int32),
            typeof(string),
            typeof(double[]),
            typeof(void)
        };
        for (int i = 0; i < t.Length; i++)
        {
            Console.WriteLine(t[i].FullName);
        }
    }
}
produces the following output:
System.Int32
System.Int32
System.String
System.Double[]
System.Void

Note that int and System.Int32 are the same type. end example]

The typeof operator can be used on a type-parameter (§25.1.1). The result is the System.Type object for the run-time type that was bound to the type-parameter. The typeof operator can also be used on a constructed type (§25.5) or an unbound generic type. The System.Type object for an unbound generic type is not the same as the System.Type object of the instance type. The instance type is always a closed constructed type at run-time so its System.Type object depends on the runtime type arguments in use, while the unbound generic type has no type arguments. [Example:

```csharp
class X<T>
{
    public static void PrintTypes()
    {
        Console.WriteLine(typeof(T).FullName);
        Console.WriteLine(typeof(X<T>).FullName);
        Console.WriteLine(typeof(X<X<T>>).FullName);
        Console.WriteLine(typeof(X<>).FullName);
    }
}
```
class M
{
    static void Main()
    {
        X<int>.PrintTypes();
        X<string>.PrintTypes();
    }
}

The above program might print:
System.Int32
X`1[[System.Int32, mscorlib, Version=2.0.3600.0, Culture=neutral, PublicKeyToken=b77a5c561934e089]]
X`1[[X`1[[System.Int32, mscorlib, Version=2.0.3600.0, Culture=neutral, PublicKeyToken=b77a5c561934e089]], CSharpEcmaExample, Version=1.0.1717.35787, Culture=neutral, PublicKeyToken=null]]
X`1
System.String
X`1[[System.String, mscorlib, Version=2.0.3600.0, Culture=neutral, PublicKeyToken=b77a5c561934e089]]
X`1[[X`1[[System.String, mscorlib, Version=2.0.3600.0, Culture=neutral, PublicKeyToken=b77a5c561934e089]], CSharpEcmaExample, Version=1.0.1717.35787, Culture=neutral, PublicKeyToken=null]]
X`1

Note that the result of `typeof(X<>)` does not depend on the type argument but the result of `typeof(X<T>)` does depend on the type argument. end example]

14.5.12 The sizeof operator

The sizeof operator returns the number of 8-bit bytes occupied by a variable of a given type. The type specified as an operand to sizeof shall be an unmanaged-type (§27.2).

```
sizeof-expression:
    sizeof ( unmanaged-type )
```

For certain predefined types the `sizeof` operator yields a constant int value as shown in the table below:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>sizeof(sbyte)</td>
<td>1</td>
</tr>
<tr>
<td>sizeof(byte)</td>
<td>1</td>
</tr>
<tr>
<td>sizeof(short)</td>
<td>2</td>
</tr>
<tr>
<td>sizeof(ushort)</td>
<td>2</td>
</tr>
<tr>
<td>sizeof(int)</td>
<td>4</td>
</tr>
<tr>
<td>sizeof(uint)</td>
<td>4</td>
</tr>
<tr>
<td>sizeof(long)</td>
<td>8</td>
</tr>
<tr>
<td>sizeof(ulong)</td>
<td>8</td>
</tr>
<tr>
<td>sizeof(char)</td>
<td>2</td>
</tr>
<tr>
<td>sizeof(float)</td>
<td>4</td>
</tr>
<tr>
<td>sizeof(double)</td>
<td>8</td>
</tr>
<tr>
<td>sizeof(bool)</td>
<td>1</td>
</tr>
<tr>
<td>sizeof(decimal)</td>
<td>16</td>
</tr>
</tbody>
</table>

For all other operand types, the `sizeof` operator is specified in §27.5.8.
14.5.13 The checked and unchecked operators

The checked and unchecked operators are used to control the *overflow-checking context* for integral-type arithmetic operations and conversions.

\[
\text{checked-expression:} \\
\quad \text{checked} \left( \text{expression} \right) \\
\text{unchecked-expression:} \\
\quad \text{unchecked} \left( \text{expression} \right)
\]

The checked operator evaluates the contained expression in a checked context, and the unchecked operator evaluates the contained expression in an unchecked context. A *checked-expression* or *unchecked-expression* corresponds exactly to a *parenthesized-expression* (§14.5.3), except that the contained expression is evaluated in the given overflow checking context.

The overflow checking context can also be controlled through the **checked** and **unchecked** statements (§15.11).

The following operations are affected by the overflow checking context established by the **checked** and **unchecked** operators and statements:

- The predefined ++ and -- unary operators (§14.5.9 and §14.6.5), when the operand type is an integral or enum type.
- The predefined ~ unary operator (§14.6.2), when the operand type is an integral type.
- The predefined +, -, *, and / binary operators (§14.7), when the operand types are integral or enum types.
- Explicit numeric conversions (§13.2.1) from one integral or enum type to another integral or enum type, or from float or double to an integral or enum type.

When one of the above operations produces a result that is too large to represent in the destination type, the context in which the operation is performed controls the resulting behavior:

- In a **checked** context, if the operation is a constant expression (§14.16), a compile-time error occurs. Otherwise, when the operation is performed at run-time, a `System.OverflowException` is thrown.
- In an **unchecked** context, the result is truncated by discarding any high-order bits that do not fit in the destination type.

For non-constant expressions (expressions that are evaluated at run-time) that are not enclosed by any **checked** or **unchecked** operators or statements, the default overflow checking context is **unchecked**, unless external factors (such as compiler switches and execution environment configuration) call for **checked** evaluation.

For constant expressions (expressions that can be fully evaluated at compile-time), the default overflow checking context is always **checked**. Unless a constant expression is explicitly placed in an **unchecked** context, overflows that occur during the compile-time evaluation of the expression always cause compile-time errors.

[Note: Developers might benefit if they exercise their code using checked mode (as well as unchecked mode). It also seems reasonable that, unless otherwise requested, the default overflow checking context is set to checked when debugging is enabled. end note]

[Example: In the following code]

```csharp
class Test
{
    static readonly int x = 1000000;
    static readonly int y = 1000000;

    static int F() {
        return checked(x * y); // Throws OverflowException
    }
}
```
C# LANGUAGE SPECIFICATION

```csharp
static int G() {
    return unchecked(x * y); // Returns -727379968
}

static int H() {
    return x * y; // Depends on default
}
}
```

no compile-time errors are reported since neither of the expressions can be evaluated at compile-time. At run-time, the `F` method throws a `System.OverflowException`, and the `G` method returns –727379968 (the lower 32 bits of the out-of-range result). The behavior of the `H` method depends on the default overflow-checking context for the compilation, but it is either the same as `F` or the same as `G`. end example]

[Example: In the following code

class Test
{
    const int x = 1000000;
    const int y = 1000000;
    static int F() {
        return checked(x * y); // Compile error, overflow
    }
    static int G() {
        return unchecked(x * y); // Returns -727379968
    }
    static int H() {
        return x * y; // Compile error, overflow
    }
}
```

the overflows that occur when evaluating the constant expressions in `F` and `H` cause compile-time errors to be reported because the expressions are evaluated in a `checked` context. An overflow also occurs when evaluating the constant expression in `G`, but since the evaluation takes place in an `unchecked` context, the overflow is not reported. end example]

The `checked` and `unchecked` operators only affect the overflow checking context for those operations that are textually contained within the “(” and “)” tokens. The operators have no effect on function members that are invoked as a result of evaluating the contained expression. [Example: In the following code

class Test
{
    static int Multiply(int x, int y) {
        return x * y;
    }
    static int F() {
        return checked(Multiply(1000000, 1000000));
    }
}
```

the use of `checked` in `F` does not affect the evaluation of `x * y` in `Multiply`, so `x * y` is evaluated in the default overflow checking context. end example]

The `unchecked` operator is convenient when writing constants of the signed integral types in hexadecimal notation. [Example:

class Test
{
    public const int AllBits = unchecked((int)0xFFFFFFFF);
    public const int HighBit = unchecked((int)0x80000000);
}
```

Both of the hexadecimal constants above are of type `uint`. Because the constants are outside the `int` range, without the `unchecked` operator, the casts to `int` would produce compile-time errors. end example]
[Note: The checked and unchecked operators and statements allow programmers to control certain aspects of some numeric calculations. However, the behavior of some numeric operators depends on their operands’ data types. For example, multiplying two decimals always results in an exception on overflow even within an explicitly unchecked construct. Similarly, multiplying two floats never results in an exception on overflow even within an explicitly checked construct. In addition, other operators are never affected by the mode of checking, whether default or explicit. As a service to programmers, it is recommended that the compiler issue a warning when there is an arithmetic expression within an explicitly checked or unchecked context (by operator or statement) that cannot possibly be affected by the specified mode of checking. Since such a warning is not required, the compiler has flexibility in determining the circumstances that merit the issuance of such warnings. end note]

14.5.14 Default value expression
A default value expression is used to obtain the default value (§12.2) of a type. Typically a default value expression is used for type parameters (§25.1.1), since it might not be known if the type parameter is a value type or a reference type. (No conversion exists from the null type (§11.2.7) to a type parameter unless the type parameter is known to be a reference type (§25.7).)

\[
\text{default-value-expression:} \\
\text{default ( type )}
\]

If the type in a default-value-expression evaluates at run-time to a reference type, the result is null converted to that type. If the type in a default-value-expression evaluates at run-time to a value type, the result is the value-type’s default value (§11.1.2).

A default-value-expression is a constant expression (§14.16) if the type is a reference type or a type parameter that is known to be a reference type (§25.7). In addition, a default-value-expression is a constant expression if the type is one of the following value types: sbyte, byte, short, ushort, int, uint, long, ulong, char, float, double, decimal, or bool.

14.5.15 Anonymous methods
An anonymous-method-expression defines an anonymous method and evaluates to a value referencing the method:

\[
\text{anonymous-method-expression:} \\
\text{delegate anonymous-method-signature_opt block}
\]

\[
\text{anonymous-method-signature:} \\
( \text{anonymous-method-parameter-list_opt} )
\]

\[
\text{anonymous-method-parameter-list:} \\
\text{anonymous-method-parameter} \\
\text{anonymous-method-parameter-list , anonymous-method-parameter}
\]

\[
\text{anonymous-method-parameter:} \\
\text{parameter-modifier_opt type identifier}
\]

The type of an anonymous delegate expression is a delegate type, which is inferred from the context of that expression. (The inference rules are described in §13.5.)

An anonymous-method-expression can be used in a delegate-creation-expression (§14.5.10.3). All other valid uses of an anonymous-method-expression depend on the implicit conversions defined in §13.5.

An anonymous-method-expression defines a new declaration space for parameters, locals and constants and a new declaration space for labels (§10.3).

14.5.15.1 Anonymous method signatures
The optional anonymous-method-signature defines the names and types of the formal parameters for the anonymous method. The scope of the parameters of the anonymous method is the block. It is a compile-time
error for the name of a parameter of the anonymous method to match the name of a local variable, local
cellent constant or parameter whose scope includes the *anonymous-method-expression*.

If an *anonymous-method-expression* has an *anonymous-method-signature*, then the set of compatible
delegate types is restricted to those that have the same parameter types and modifiers, in the same order
(§13.5). In contrast to method groups, contra-variance of anonymous method parameter types is not
supported (§14.5.10.3). If an *anonymous-method-expression* doesn’t have an *anonymous-method-signature*,
then the set of compatible delegate types is restricted to those that have no *out* parameters.

Note that an *anonymous-method-signature* cannot include attributes or a *parameter-array*. Nevertheless, an
*anonymous-method-signature* may be compatible with a delegate type whose *formal-parameter-list* contains
a *parameter-array*.

14.5.15.2 Anonymous method blocks

The *block* of an *anonymous-method-expression* is subject to the following rules:

- If the anonymous method includes a signature, the parameters specified in the signature are available in
  the *block*. If the anonymous method has no signature, it can be converted to a delegate type having
  parameters (§13.5), but the parameters cannot be accessed in the *block*.

- Except for *ref* or *out* parameters specified in the signature (if any) of the nearest enclosing anonymous
  method, it is a compile-time error for the *block* to access a *ref* or *out* parameter.

- When the type of *this* is a struct type, it is a compile-time error for the *block* to access *this*. This is
  true whether the access is explicit (as in *this.x*) or implicit (as in *x*, where *x* is an instance member of
  the struct). This rule simply prohibits such access and does not affect whether member lookup results in
  a member of the struct.

- The *block* has access to the outer variables (§14.5.15.3) of the anonymous method. Access of an outer
  variable will reference the instance of the variable that is active at the time the *anonymous-method-
  expression* is evaluated (§14.5.15.4).

- It is a compile-time error for the *block* to contain a *goto* statement, *break* statement, or *continue*
  statement whose target is outside the *block* or within the *block* of a contained anonymous method.

- A *return* statement in the *block* returns control from an invocation of the nearest enclosing anonymous
  method, not from the enclosing function member. An expression specified in a *return* statement shall
  be compatible with the delegate type to which the nearest enclosing *anonymous-method-expression* is
  converted (§14.5.15.4).

It is explicitly unspecified whether there is any way to execute the *block* of an anonymous method other than
through evaluation and invocation of the *anonymous-method-expression*. In particular, a compiler might
choose to implement an anonymous method by synthesizing one or more named methods or types. The
names of any such synthesized elements shall be in the space reserved for implementations (that is, the
names shall contain two consecutive underscore characters).

14.5.15.3 Outer variables

Any local variable, value parameter, or parameter array whose scope includes an *anonymous-method-
expression* is called an *outer variable* of that *anonymous-method-expression*. In an instance function
member of a class, the *this* value is considered a value parameter and is an outer variable of any
*anonymous-method-expression* contained within that function member.

14.5.15.3.1 Captured outer variables

When an outer variable is referenced by an anonymous method, the outer variable is said to have been
captured by the anonymous method. Ordinarily, the lifetime of a local variable is limited to execution of the
block or statement with which it is associated (§12.1.7). However, the lifetime of a captured outer variable is
extended at least until the delegate referring to the anonymous method becomes eligible for garbage
collection.
Example: In the following code

```c#
using System;
delegate int D();
class Test
{
    static D F()
    {
        int x = 0;
        D result = delegate { return ++x; };
        return result;
    }
    static void Main()
    {
        D d = F();
        Console.WriteLine(d());
        Console.WriteLine(d());
        Console.WriteLine(d());
    }
}
```

the local variable `x` is captured by the anonymous method, and the lifetime of `x` is extended at least until the delegate returned from `F` becomes eligible for garbage collection. Since each invocation of the anonymous method operates on the same instance of `x`, the output of the example is:

```
1
2
3
```

end example]

14.5.15.3.2 Instantiation of local variables

A local variable is considered to be **instantiated** when execution enters the scope of the variable. [Example: When the following method is invoked, the local variable `x` is instantiated and initialized three times—once each iteration of the loop.

```c#
static void F()
{
    for (int i = 0; i < 3; i++)
    {
        int x = i * 2 + 1;
        ...
    }
}
```

However, moving the declaration of `x` outside the loop results in a single instantiation of `x`:

```c#
static void F()
{
    int x;
    for (int i = 0; i < 3; i++)
    {
        x = i * 2 + 1;
        ...
    }
}
```

end example]

Ordinarily, there is no way to observe exactly how often a local variable is instantiated—because the lifetimes of the instantiations are disjoint, it is possible for each instantiation to simply use the same storage location. However, when an anonymous method captures a local variable, the effects of instantiation become apparent. [Example: The example

```c#
using System;
delegate void D();
```
class Test {
    static D[] F() {
        D[] result = new D[3];
        for (int i = 0; i < 3; i++) {
            int x = i * 2 + 1;
            result[i] = delegate { Console.WriteLine(x); };
        }
        return result;
    }
    static void Main() {
        foreach (D d in F()) d();
    }
}

produces the output:
1
3
5

However, when the declaration of x is moved outside the loop:

    static D[] F() {
        D[] result = new D[3];
        int x;
        for (int i = 0; i < 3; i++) {
            x = i * 2 + 1;
            result[i] = delegate { Console.WriteLine(x); };
        }
        return result;
    }

the output is:
5
5
5

Note that the three delegates created in the version of F directly above will be equal according to the equality operator (§14.9.8). Furthermore, note that the compiler is permitted (but not required) to optimize the three instantiations into a single delegate instance (§14.5.15.4).

It is possible for anonymous method delegates to share some captured variables yet have separate instances of others. [Example: If F is changed to

    static D[] F() {
        D[] result = new D[3];
        int x = 0;
        for (int i = 0; i < 3; i++) {
            int y = 0;
            result[i] = delegate { Console.WriteLine("{0} {1}" + , ++x, ++y); };
        }
        return result;
    }

the three delegates capture the same instance of x but separate instances of y, and the output is:

1 1
2 1
3 1

end example]}

Separate anonymous methods can capture the same instance of an outer variable. [Example: In the following code:

    using System;
    delegate void Setter(int value);
    delegate int Getter();
class Test
{
    static void Main()
    {
        int x = 0;
        Setter s = delegate(int value) { x = value; };
        Getter g = delegate { return x; };
        s(5);
        Console.WriteLine(g());
        s(10);
        Console.WriteLine(g());
    }
}

The two anonymous methods capture the same instance of the local variable x, and they can thus “communicate” through that variable. The output of the example is:

5
10

end example]

14.5.15.4 Anonymous method evaluation

The run-time evaluation of an anonymous-method-expression produces a delegate instance which references the anonymous method and the (possibly empty) set of captured outer variables that are active at the time of the evaluation. When a delegate resulting from an anonymous-method-expression is invoked, the body of the anonymous method is executed. The code in the body is executed using the set of captured outer variables referenced by the delegate.

The invocation list of a delegate produced from an anonymous-method-expression contains a single entry. The exact target object and target method of the delegate are unspecified. In particular, it is unspecified whether the target object of the delegate is null, the this value of the enclosing function member, or some other object.

Evaluation of semantically identical anonymous-method-expressions with the same (possibly empty) set of captured outer variable instances is permitted (but not required) to return the same delegate instance. The term “semantically identical” is used here to mean that execution of the anonymous methods will produce, in all cases, the same effects given the same arguments. [Example: This rule permits code such as the following to be optimized.

delegate double Function(double x);

class Test
{
    static double[] Apply(double[] vector, Function func) {
        double[] result = new double[vector.Length];
        for (int i = 0; i < vector.Length; i++) {
            result[i] = func(vector[i]);
        }
        return result;
    }

    static void F(double[] vx, double[] vy) {
        double[] rx = Apply(vx, delegate(double x) {
            return Math.Sin(x);
        });
        double[] ry = Apply(vy, delegate(double y) {
            return Math.Sin(y);
        });
        ...}
}

Since the two anonymous method delegates have the same (empty) set of captured outer variables, and since the anonymous methods are semantically identical, the compiler is permitted to have the delegates refer to the same target method. Indeed, the compiler is permitted to return the very same delegate instance from both anonymous method expressions.
14.5.15.5 Implementation example

Note: This subclause describes a possible implementation of anonymous methods in terms of standard C# constructs. The implementation described here is by no means a mandated implementation, nor is it the only one possible.

The remainder of this subclause gives several examples of code that contains anonymous methods with different characteristics. For each example, a corresponding translation to code that uses only standard C# constructs is provided. In the examples, the identifier D is assumed to represent the following delegate type:

```csharp
public delegate void D();
```

The simplest form of an anonymous method is one that captures no outer variables:

```csharp
class Test
{
    static void F()
    {
        D d = delegate { Console.WriteLine("test"); };
    }
}
```

This can be translated to a delegate instantiation that references a compiler-generated static method in which the code of the anonymous method is placed:

```csharp
class Test
{
    static void F()
    {
        D d = new D(__Method1);
    }

    static void __Method1()
    {
        Console.WriteLine("test");
    }
}
```

In the following example, the anonymous method references instance members of this:

```csharp
class Test
{
    int x;
    void F()
    {
        D d = delegate { Console.WriteLine(x); };
    }
}
```

This can be translated to a compiler-generated instance method containing the code of the anonymous method:

```csharp
class Test
{
    int x;
    void F()
    {
        D d = new D(__Method1);
    }

    void __Method1()
    {
        Console.WriteLine(x);
    }
}
```

In this example, the anonymous method captures a local variable:
class Test
{
    void F()
    {
        int y = 123;
        D d = delegate { Console.WriteLine(y); };
    }
}

The lifetime of the local variable shall now be extended to at least the lifetime of the anonymous method delegate. This can be achieved by “lifting” the local variable into a field of a compiler-generated class. Instantiation of the local variable (§14.5.15.3.2) then corresponds to creating an instance of the compiler-generated class, and accessing the local variable corresponds to accessing a field in the instance of the compiler-generated class. Furthermore, the anonymous method becomes an instance method of the compiler-generated class:

```csharp
class Test
{
    void F()
    {
        __Locals1 __locals1 = new __Locals1();
        __locals1.y = 123;
        D d = new D(__locals1.__Method1);
    }
}
```

class __Locals1
{
    public int y;
    public void __Method1()
    {
        Console.WriteLine(y);
    }
}

Finally, the following anonymous method captures this as well as two local variables with different lifetimes:

```csharp
class Test
{
    void F()
    {
        int x;
        int y = 123;
        for (int i = 0; i < 10; i++)
        {
            int z = i * 2;
            D d = delegate { Console.WriteLine(x + y + z); };
        }
    }
}
```

Here, a compiler-generated class is created for each statement block in which locals are captured such that the locals in the different blocks can have independent lifetimes. An instance of __Locals2, the compiler-generated class for the inner statement block, contains the local variable z and a field that references an instance of __Locals1. An instance of __Locals1, the compiler-generated class for the outer statement block, contains the local variable y and a field that references this of the enclosing function member. With these data structures it is possible to reach all captured outer variables through an instance of __Locals2, and the code of the anonymous method can thus be implemented as an instance method of that class.
class Test
{
    void F()
    {
        __Locals1 __locals1 = new __Locals1();
        __locals1.__this = this;
        __locals1.y = 123;
        for (int i = 0; i < 10; i++)
        {
            __Locals2 __locals2 = new __Locals2();
            __locals2.__locals1 = __locals1;
            __locals2.z = i * 2;
            D d = new D(__locals2.__Method1);
        }
    }
}

class __Locals1
{
    public Test __this;
    public int y;
}

class __Locals2
{
    public __Locals1 __locals1;
    public int z;
    public void __Method1()
    {
        Console.WriteLine(__locals1.__this.x + __locals1.y + z);
    }
}

end note]

14.6 Unary expressions

unary-expression:
    primary-expression
    + unary-expression
    - unary-expression
    ! unary-expression
    ~ unary-expression
    pre-increment-expression
    pre-decrement-expression
    cast-expression

14.6.1 Unary plus operator

For an operation of the form +x, unary operator overload resolution (§14.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined unary plus operators are:

int operator +(int x);
uint operator +(uint x);
long operator +(long x);
ulong operator +(ulong x);
float operator +(float x);
double operator +(double x);
decimal operator +(decimal x);

For each of these operators, the result is simply the value of the operand.

Lifted (§14.2.7) forms of the unlifted predefined unary plus operators defined above are also predefined.
14.6.2 Unary minus operator
For an operation of the form \(-x\), unary operator overload resolution (§14.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined negation operators are:

- **Integer negation:**
  
  int operator -(int x);
  long operator -(long x);

  The result is computed by subtracting \(x\) from zero. In a checked context, if the value of \(x\) is the smallest int or long \((-2^{31} or -2^{63}, respectively\), a System.OverflowException is thrown. In an unchecked context, if the value of \(x\) is the smallest int or long, the result is that same value and the overflow is not reported.

  If the operand of the negation operator is of type uint, it is converted to type long, and the type of the result is long. An exception is the rule that permits the int value \(-2147483648 (\sim-2^{31})\) to be written as a decimal integer literal (§9.4.4.2).

- **Negation of ulong is an error:**

  void operator -(ulong x);

  Selection of this operator by unary operator overload resolution (§14.2.3) always results in a compile-time error. Consequently, if the operand of the negation operator is of type ulong, a compile-time error occurs. An exception is the rule that permits the long value \(-9223372036854775808 (\sim-2^{63})\) to be written as a decimal integer literal (§9.4.4.2).

- **Floating-point negation:**

  float operator -(float x);
  double operator -(double x);

  The result is the value of \(x\) with its sign inverted. If \(x\) is NaN, the result is also NaN.

- **Decimal negation:**

  decimal operator -(decimal x);

  The result is computed by subtracting \(x\) from zero.

  Decimal negation is equivalent to using the unary minus operator of type System.Decimal.

Lifted (§14.2.7) forms of the unlifted predefined unary minus operators defined above are also predefined.

14.6.3 Logical negation operator
For an operation of the form \(!x\), unary operator overload resolution (§14.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. Only one predefined logical negation operator exists:

  bool operator !(bool x);

  This operator computes the logical negation of the operand: If the operand is true, the result is false. If the operand is false, the result is true.

Lifted (§14.2.7) forms of the unlifted predefined logical negation operator defined above are also predefined.

14.6.4 Bitwise complement operator
For an operation of the form \(~x\), unary operator overload resolution (§14.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined bitwise complement operators are:

  int operator ~(int x);
  uint operator ~(uint x);
  long operator ~(long x);
  ulong operator ~(ulong x);
For each of these operators, the result of the operation is the bitwise complement of \( x \).

Every enumeration type \( E \) implicitly provides the following bitwise complement operator:

\[
E \ operator \ ~(E \ x);
\]

The result of evaluating \( \neg x \), where \( x \) is an expression of an enumeration type \( E \) with an underlying type \( U \), is exactly the same as evaluating \( \text{unchecked}((E)(\neg(U)x)) \). This operator is only considered by unary operator overload resolution when the operand type is the enum type \( E \) (§14.2.3).

Lifted (§14.2.7) forms of the unlifted predefined bitwise complement operators defined above are also predefined.

### 14.6.5 Prefix increment and decrement operators

**pre-increment-expression:**

\[
++ \ \text{unary-expression}
\]

**pre-decrement-expression:**

\[
-- \ \text{unary-expression}
\]

The operand of a prefix increment or decrement operation shall be an expression classified as a variable, a property access, or an indexer access. The result of the operation is a value of the same type as the operand.

If the operand of a prefix increment or decrement operation is a property or indexer access, the property or indexer shall have both a `get` and a `set` accessor. If this is not the case, a compile-time error occurs.

Unary operator overload resolution (§14.2.3) is applied to select a specific operator implementation. Predefined `++` and `--` operators exist for the following operand types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type. The result type of each of these predefined operators is the same as the operand type. The predefined `++` operators return the value produced by adding 1 to the operand, and the predefined `--` operators return the value produced by subtracting 1 from the operand. In a `checked` context, if the result of this addition or subtraction is outside the range of the result type, a `System.OverflowException` is thrown.

There shall be an implicit conversion from the return type of the selected unary operator to the type of the `primary-expression`, otherwise a compile-time error occurs.

The run-time processing of a prefix increment or decrement operation of the form `++x` or `--x` consists of the following steps:

- If \( x \) is classified as a variable:
  - \( x \) is evaluated to produce the variable.
  - The value of \( x \) is converted to the operand type of the selected operator and the operator is invoked with this value as its argument.
  - The value returned by the operator is converted to the type of \( x \). The resulting value is stored in the location given by the evaluation of \( x \) and becomes the result of the operation.

- If \( x \) is classified as a property or indexer access:
  - The instance expression (if \( x \) is not `static`) and the argument list (if \( x \) is an indexer access) associated with \( x \) are evaluated, and the results are used in the subsequent `get` and `set` accessor invocations.
  - The `get` accessor of \( x \) is invoked.
  - The value returned by the get accessor is converted to the operand type of the selected operator and operator is invoked with this value as its argument.
  - The value returned by the operator is converted to the type of \( x \). The `set` accessor of \( x \) is invoked with this value as its `value` argument. This value also becomes the result of the operation.
The ++ and -- operators also support postfix notation (§14.5.9). The result of x++ or x-- is the value of x before the operation, whereas the result of ++x or --x is the value of x after the operation. In either case, x itself has the same value after the operation.

An operator ++ or operator -- implementation can be invoked using either postfix or prefix notation. It is not possible to have separate operator implementations for the two notations.

Lifted (§14.2.7) forms of the unlifted predefined prefix increment and decrement operators defined above are also predefined.

14.6.6 Cast expressions

A cast-expression is used to convert explicitly an expression to a given type.

\[
\text{cast-expression:} \quad \left( \text{type } \right) \text{unary-expression}
\]

A cast-expression of the form (T)E, where T is a type and E is a unary-expression, performs an explicit conversion (§13.2) of the value of E to type T. If no explicit conversion exists from the type of E to T, a compile-time error occurs. Otherwise, the result is the value produced by the explicit conversion. The result is always classified as a value, even if E denotes a variable.

The grammar for a cast-expression leads to certain syntactic ambiguities. [Example: The expression (x)–y could either be interpreted as a cast-expression (a cast of –y to type x) or as an additive-expression combined with a parenthesized-expression (which computes the value x – y). end example]

To resolve cast-expression ambiguities, the following rule exists: A sequence of one or more tokens (§9.4) enclosed in parentheses is considered the start of a cast-expression only if at least one of the following are true:

- The sequence of tokens is correct grammar for a type, but not for an expression.
- The sequence of tokens is correct grammar for a type, and the token immediately following the closing parentheses is the token “~”, the token “!” the token “C”, an identifier (§9.4.1), a literal (§9.4.4), or any keyword (§9.4.3) except as and is.

The term “correct grammar” above means only that the sequence of tokens shall conform to the particular grammatical production. It specifically does not consider the actual meaning of any constituent identifiers. [Example: If x and y are identifiers, then x . y is correct grammar for a type, even if x . y doesn’t actually denote a type. end example]

[Note: From the disambiguation rule, it follows that, if x and y are identifiers, (x)y, (x)(y), and (x)(–y) are cast-expressions, but (x)–y is not, even if x identifies a type. However, if x is a keyword that identifies a predefined type (such as int), then all four forms are cast-expressions (because such a keyword could not possibly be an expression by itself). end note]

14.7 Arithmetic operators

The *, /, %, +, and – operators are called the arithmetic operators.

\[
multiplicative-expression:
\quad \text{unary-expression} \\
multiplicative-expression \ast \text{unary-expression} \\
multiplicative-expression \div \text{unary-expression} \\
multiplicative-expression \mod \text{unary-expression}
\]

\[
additive-expression:
\quad \text{multiplicative-expression} \\
\text{additive-expression} + \text{multiplicative-expression} \\
\text{additive-expression} - \text{multiplicative-expression}
\]
14.7.1 Multiplication operator

For an operation of the form \( x \times y \), binary operator overload resolution (§14.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined multiplication operators are listed below. The operators all compute the product of \( x \) and \( y \).

- Integer multiplication:
  
  ```csharp
  int operator *(int x, int y);
  uint operator *(uint x, uint y);
  long operator *(long x, long y);
  ulong operator *(ulong x, ulong y);
  void operator *(long x, ulong y);
  void operator *(ulong x, long y);
  ```
  
  The operators with `void` return type always produce a compile-time error. Consequently, it is an error for one operand to be of type `long` and the other to be of type `ulong`.

  In a checked context, if the product is outside the range of the result type, a `System.OverflowException` is thrown. In an unchecked context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- Floating-point multiplication:
  
  ```csharp
  float operator *(float x, float y);
  double operator *(double x, double y);
  ```
  
  The product is computed according to the rules of IEC 60559 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN’s. In the table, \( x \) and \( y \) are positive finite values. \( z \) is the result of \( x \times y \), rounded to the nearest representable value. If the magnitude of the result is too large for the destination type, \( z \) is infinity. Because of rounding, \( z \) may be zero even though neither \( x \) nor \( y \) is zero.

- Decimal multiplication:
  
  ```csharp
  decimal operator *(decimal x, decimal y);
  ```
  
  If the magnitude of the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. Because of rounding, the result may be zero even though neither operand is zero. The scale of the result, before any rounding, is the sum of the scales of the two operands.

  Decimal multiplication is equivalent to using the multiplication operator of type `System.Decimal`.

  Lifted (§14.2.7) forms of the unlifted predefined multiplication operators defined above are also predefined.

14.7.2 Division operator

For an operation of the form \( x \div y \), binary operator overload resolution (§14.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.
The predefined division operators are listed below. The operators all compute the quotient of \( x \) and \( y \).

- **Integer division:**
  - `int operator /(int x, int y);`
  - `uint operator /(uint x, uint y);`
  - `long operator /(long x, long y);`
  - `ulong operator /(ulong x, ulong y);`
  - `void operator /(long x, ulong y);`
  - `void operator /(ulong x, long y);`

  The operators with `void` return type always produce a compile-time error. Consequently, it is an error for one operand to be of type `long` and the other to be of type `ulong`.

  If the value of the right operand is zero, a `System.DivideByZeroException` is thrown.

  The division rounds the result towards zero, and the absolute value of the result is the largest possible integer that is less than the absolute value of the quotient of the two operands. The result is zero or positive when the two operands have the same sign and zero or negative when the two operands have opposite signs.

  If the left operand is the smallest `int` or `long` value (\(-2^{31}\) or \(-2^{63}\), respectively) and the right operand is \(-1\), an overflow occurs. In a checked context, this causes a `System.ArithmeticException` (or a subclass thereof) to be thrown. In an unchecked context, it is implementation-defined as to whether a `System.ArithmeticException` (or a subclass thereof) is thrown or the overflow goes unreported with the resulting value being that of the left operand.

- **Floating-point division:**
  - `float operator /(float x, float y);`
  - `double operator /(double x, double y);`

  The quotient is computed according to the rules of IEC 60559 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN’s. In the table, \( x \) and \( y \) are positive finite values. \( z \) is the result of \( x / y \), rounded to the nearest representable value. If the magnitude of the result is too large for the destination type, \( z \) is infinity. Because of rounding, \( z \) may still be zero even though \( x \) is not zero and \( y \) is not infinite.

- **Decimal division:**
  - `decimal operator /(decimal x, decimal y);`

  If the value of the right operand is zero, a `System.DivideByZeroException` is thrown. If the magnitude of the resulting value is too large to represent in the decimal format, a `System.OverflowException` is thrown. Because of rounding, the result may be zero even though the first operand is not zero. The scale of the result, before any rounding, is the closest scale to the preferred scale which will preserve a result equal to the exact result. The preferred scale is the scale of \( x \) less the scale of \( y \).

  Decimal division is equivalent to using the division operator of type `System.Decimal`.

Lifted (§14.2.7) forms of the unlifted predefined division operators defined above are also predefined.
14.7.3 Remainder operator

For an operation of the form \( x \% y \), binary operator overload resolution (§14.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined remainder operators are listed below. The operators all compute the remainder of the division between \( x \) and \( y \).

- **Integer remainder:**
  ```csharp
  int operator %(int x, int y);
  uint operator %(uint x, uint y);
  long operator %(long x, long y);
  ulong operator %(ulong x, ulong y);
  void operator %(long x, ulong y);
  void operator %(ulong x, long y);
  ```

  The operators with `void` return type always produce a compile-time error. Consequently, it is an error for one operand to be of type `long` and the other to be of type `ulong`.

  The result of \( x \% y \) is the value produced by \( x - (x / y) \times y \). If \( y \) is zero, a `System.DivideByZeroException` is thrown.

  If the left operand is the smallest `int` or `long` value (\(-2^{31}\) or \(-2^{63}\), respectively) and the right operand is \(-1\), it is implementation-defined as to whether a `System.ArithmeticException` (or a subclass thereof) is thrown. A conforming implementation shall not throw an exception for \( x \% y \) in any case where \( x / y \) does not throw an exception.

- **Floating-point remainder:**
  ```csharp
  float operator %(float x, float y);
  double operator %(double x, double y);
  ```

  The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN’s. In the table, \( x \) and \( y \) are positive finite values. \( z \) is the result of \( x \% y \) and is computed as \( x - n \times y \), rounded to the nearest representable value, where \( n \) is the largest integer that is less than or equal to \( x / y \). This method of computing the remainder is analogous to that used for integer operands, but differs from the IEC 60559 definition (in which \( n \) is the integer closest to \( x / y \)).

A conforming implementation shall not throw an exception for \( x \% y \) in any case where \( x / y \) does not throw an exception.   Lifted (§14.2.7) forms of the unlifted predefined remainder operators defined above are also predefined.
14.7.4 Addition operator

For an operation of the form \( x + y \), binary operator overload resolution (§14.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined addition operators are listed below. For numeric and enumeration types, the predefined addition operators compute the sum of the two operands. When one or both operands are of type `string`, the predefined addition operators concatenate the string representation of the operands.

- **Integer addition:**
  ```
  int operator +(int x, int y);
  uint operator +(uint x, uint y);
  long operator +(long x, long y);
  ulong operator +(ulong x, ulong y);
  ```

  The operators with `void` return type always produce a compile-time error. Consequently, it is an error for one operand to be of type `long` and the other to be of type `ulong`.

  In a checked context, if the sum is outside the range of the result type, a `System.OverflowException` is thrown. In an unchecked context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- **Floating-point addition:**
  ```
  float operator +(float x, float y);
  double operator +(double x, double y);

  The sum is computed according to the rules of IEC 60559 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN’s. In the table, \( x \) and \( y \) are nonzero finite values, and \( z \) is the result of \( x + y \), rounded to the nearest representable value. If \( x \) and \( y \) have the same magnitude but opposite signs, \( z \) is positive zero. If the magnitude of \( x + y \) is too large to represent in the destination type, \( z \) is an infinity with the same sign as \( x + y \).

- **Decimal addition:**
  ```
  decimal operator +(decimal x, decimal y);
  ```

  If the magnitude of the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands.

  Decimal addition is equivalent to using the addition operator of type `System.Decimal`.

- **Enumeration addition.** Every enumeration type implicitly provides the following predefined operators, where \( E \) is the enum type, and \( U \) is the underlying type of \( E \):
  ```
  E operator +(E x, U y);
  E operator +(U x, E y);
  ```

  The operators are evaluated exactly as \((E)(U)x + (U)y\). These operators are only considered by overload resolution (§14.2.4) when one of the actual operands is of type \( E \).
• String concatenation:
  ```csharp
  string operator +(string x, string y);
  string operator +(string x, object y);
  string operator +(object x, string y);
  ```

The binary + operator performs string concatenation when one or both operands are of type `string`. If
an operand of string concatenation is `null`, an empty string is substituted. Otherwise, any non-string
operand is converted to its string representation by invoking the virtual `ToString` method inherited
from type `object`. If `ToString` returns `null`, an empty string is substituted. [Example:
```csharp
using System;
class Test
{
  static void Main()
  {
    string s = null;
    Console.WriteLine("s = "+s+"<"); // displays s = ><
    int i = 1;
    Console.WriteLine("i = "+i); // displays i = 1
    float f = 1.2300E+15F;
    Console.WriteLine("f = "+f); // displays f = 1.23E+15
    decimal d = 2.900m;
    Console.WriteLine("d = "+d); // displays d = 2.900
  }
}
end example]

The result of the string concatenation operator is a string that consists of the characters of the left
operand followed by the characters of the right operand. The string concatenation operator never returns
a `null` value. A `System.OutOfMemoryException` can be thrown if there is not enough memory
available to allocate the resulting string.

• Delegate combination. Every delegate type implicitly provides the following predefined operator, where
`D` is the delegate type:
  ```csharp
  D operator +(D x, D y);
  ```

The binary + operator performs delegate combination when both operands are convertible to some
delegate type `D`. (If the operands have different delegate types, overload resolution finds no applicable
operator and a compile-time error occurs.) This operator is only considered by overload resolution
(§14.2.4) when one of the actual operands is of type `D`. If the first operand is `null`, the result of the
operation is the value of the second operand (even if that is also `null`). Otherwise, if the second operand
is `null`, then the result of the operation is the value of the first operand. Otherwise, the result of the
operation is a new delegate instance whose invocation list consists of the elements in the invocation list
of the first operand, followed by the elements in the invocation list of the second operand. That is, the
invocation list of the resulting delegate is the concatenation of the invocation lists of the two operands.
[Note: For examples of delegate combination, see §14.7.5 and §22.3. Since `System.Delegate` is not a
delegate type, `operator +` is not defined for it. end note]

Lifted (§14.2.7) forms of the unlifted predefined addition operators defined above are also predefined.

### 14.7.5 Subtraction operator

For an operation of the form `x – y`, binary operator overload resolution (§14.2.4) is applied to select a
specific operator implementation. The operands are converted to the parameter types of the selected
operator, and the type of the result is the return type of the operator.

The predefined subtraction operators are listed below. The operators all subtract `y` from `x`.

• Integer subtraction:
14 Expressions

```c
int operator -(int x, int y);
uint operator -(uint x, uint y);
long operator -(long x, long y);
ulong operator -(ulong x, ulong y);
void operator -(long x, ulong y);
void operator -(ulong x, long y);
```

The operators with `void` return type always produce a compile-time error. Consequently, it is an error for one operand to be of type `long` and the other to be of type `ulong`.

In a checked context, if the difference is outside the range of the result type, a `System.OverflowException` is thrown. In an unchecked context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- **Floating-point subtraction:**
  ```c
  float operator -(float x, float y);
double operator -(double x, double y);
  ```

  The difference is computed according to the rules of IEC 60559 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaNs. In the table, `x` and `y` are nonzero finite values, and `z` is the result of `x – y`, rounded to the nearest representable value.

  If `x` and `y` are equal, `z` is positive zero. If the magnitude of `x – y` is too large to represent in the destination type, `z` is an infinity with the same sign as `x – y`.

- **Decimal subtraction:**
  ```c
decimal operator -(decimal x, decimal y);
  ```

  If the magnitude of the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands.

  Decimal subtraction is equivalent to using the subtraction operator of type `System.Decimal`.

- **Enumeration subtraction.** Every enumeration type implicitly provides the following predefined operator, where `E` is the enum type, and `U` is the underlying type of `E`:

  ```c
  U operator -(E x, E y);
  ```

  This operator is evaluated exactly as `((U)x – (U)y)`. In other words, the operator computes the difference between the ordinal values of `x` and `y`, and the type of the result is the underlying type of the enumeration.

  ```c
  E operator -(E x, U y);
  ```

  This operator is evaluated exactly as `((U)x – y)`. In other words, the operator subtracts a value from the underlying type of the enumeration, yielding a value of the enumeration.

  These operators are only considered by overload resolution (§14.2.4) when one of the actual operands is of type `E`.

- **Delegate removal.** Every delegate type implicitly provides the following predefined operator, where `D` is the delegate type:
D operator -(D x, D y);

The binary - operator performs delegate removal when both operands are convertible to some delegate type D. (If the operands have different delegate types, overload resolution finds no applicable operator and a compile-time error occurs.) This operator is only considered by overload resolution (§14.2.4) when one of the actual operands is of type D. If the first operand is null, the result of the operation is null. Otherwise, if the second operand is null, then the result of the operation is the value of the first operand. Otherwise, both operands represent invocation lists (§22.1) having one or more entries, and the result is a new invocation list consisting of the first operand’s list with the second operand’s entries removed from it, provided the second operand’s list is a proper contiguous sublist of the first’s. (For determining sublist equality, corresponding entries are compared as for the delegate equality operator (§14.9.8).) Otherwise, the result is the value of the left operand. Neither of the operands’ lists is changed in the process. If the second operand’s list matches multiple sublists of contiguous entries in the first operand’s list, the right-most matching sublist of contiguous entries is removed. If removal results in an empty list, the result is null. [Example:

```csharp
using System;
delegate void D(int x);
class Test {
    public static void M1(int i) { /* … */ }
    public static void M2(int i) { /* … */ }
}
class Demo {
    static void Main() {
        D cd1 = new D(Test.M1);
        D cd2 = new D(Test.M2);
        D cd3 = cd1 + cd2 + cd2 + cd1; // M1 + M2 + M2 + M1
        cd3 -= cd1; // => M1 + M2 + M2
        cd3 -= cd1 + cd2 + cd2 + cd1; // M1 + M2 + M2 + M1
        cd3 -= cd1 + cd2; // => M2 + M1
        cd3 -= cd1 + cd2 + cd2 + cd1; // M1 + M2 + M2 + M1
        cd3 -= cd1 + cd2 + cd1; // => M1 + M1
        cd3 -= cd1 + cd2 + cd1; // => M1 + M2 + M1
        cd3 -= cd1 + cd2; // => M1 + M2 + M1
        cd3 -= cd1 + cd1; // => M1 + M2 + M2 + M1
    }
}
end example]

Lifted (§14.2.7) forms of the unlifted predefined subtraction operators defined above are also predefined.

14.8 Shift operators

The << and >> operators are used to perform bit shifting operations.

```
shift-expression:
    additive-expression
    shift-expression  <<  additive-expression
    shift-expression  right-shift  additive-expression
```

For an operation of the form x << count or x >> count, binary operator overload resolution (§14.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

When declaring an overloaded shift operator, the type of the first operand shall always be the class or struct containing the operator declaration, and the type of the second operand shall always be int.
The predefined shift operators are listed below.

- **Shift left:**
  ```
  int operator <<(int x, int count);
  uint operator <<(uint x, int count);
  long operator <<(long x, int count);
  ulong operator <<(ulong x, int count);
  ```
  The `<<` operator shifts `x` left by a number of bits computed as described below. The high-order bits outside the range of the result type of `x` are discarded, the remaining bits are shifted left, and the low-order empty bit positions are set to zero.

- **Shift right:**
  ```
  int operator >> (int x, int count);
  uint operator >> (uint x, int count);
  long operator >> (long x, int count);
  ulong operator >> (ulong x, int count);
  ```
  The `>>` operator shifts `x` right by a number of bits computed as described below. When `x` is of type `int` or `long`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero if `x` is non-negative and set to one if `x` is negative. When `x` is of type `uint` or `ulong`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero.

For the predefined operators, the number of bits to shift is computed as follows:

- When the type of `x` is `int` or `uint`, the shift count is given by the low-order five bits of `count`. In other words, the shift count is computed from `count & 0x1F`.
- When the type of `x` is `long` or `ulong`, the shift count is given by the low-order six bits of `count`. In other words, the shift count is computed from `count & 0x3F`.

If the resulting shift count is zero, the shift operators simply return the value of `x`.

Shift operations never cause overflows and produce the same results in checked and unchecked contexts. When the left operand of the `>>` operator is of a signed integral type, the operator performs an arithmetic shift right wherein the value of the most significant bit (the sign bit) of the operand is propagated to the high-order empty bit positions. When the left operand of the `>>` operator is of an unsigned integral type, the operator performs a logical shift right wherein high-order empty bit positions are always set to zero. To perform the opposite operation of that inferred from the operand type, explicit casts can be used. [Example: If `x` is a variable of type `int`, the operation `unchecked((int)((uint)x >> y))` performs a logical shift right of `x`. end example] Lifted (§14.2.7) forms of the unlifted predefined shift operators defined above are also predefined.

### 14.9 Relational and type-testing operators

The `==`, `!=`, `<`, `>`, `<=`, `>=`, `is` and `as` operators are called the relational and type-testing operators.

```
relational-expression:
  shift-expression
  relational-expression < shift-expression
  relational-expression > shift-expression
  relational-expression <= shift-expression
  relational-expression >= shift-expression
  relational-expression is type
  relational-expression as type
```
equality-expression:
  relational-expression
  equality-expression == relational-expression
  equality-expression != relational-expression

The `is` operator is described in §14.9.10 and the `as` operator is described in §14.9.11.

The `==`, `!=`, `<`, `<=`, `>`, `>=` operators are *comparison operators*. For an operation of the form `x op y`, where `op` is a comparison operator, overload resolution (§14.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator. If both operands of an equality-expression have the null type (§11.2.7) (and hence the null value as well), then overload resolution is not performed and the expression evaluates to a constant value of `true` or `false` according to whether the operator is `==` or `!=`.

The predefined comparison operators are described in the following subclauses. All predefined comparison operators return a result of type `bool`, as described in the following table. All predefined comparison operators return a result of type `bool`, as described in the following table.

<table>

### 14.9.1 Integer comparison operators

The predefined integer comparison operators are:

```csharp
bool operator ==(int x, int y);
bool operator ==(uint x, uint y);
bool operator ==(long x, long y);
bool operator ==(ulong x, ulong y);
void operator ==(long x, ulong y);
void operator ==(ulong x, long y);

bool operator !=(int x, int y);
bool operator !=(uint x, uint y);
bool operator !=(long x, long y);
bool operator !=(ulong x, ulong y);
void operator !=(long x, ulong y);
void operator !=(ulong x, long y);

bool operator <(int x, int y);
bool operator <(uint x, uint y);
bool operator <(long x, long y);
bool operator <(ulong x, ulong y);
void operator <(long x, ulong y);
void operator <(ulong x, long y);

bool operator >(int x, int y);
bool operator >(uint x, uint y);
bool operator >(long x, long y);
bool operator >(ulong x, ulong y);
void operator >(long x, ulong y);
void operator >(ulong x, long y);
```
Expressions

bool operator <=(int x, int y);
bool operator <=(uint x, uint y);
bool operator <=(long x, long y);
bool operator <=(ulong x, ulong y);
void operator <=(long x, ulong y);
void operator <=(ulong x, long y);

Each of these operators compares the numeric values of the two integer operands and returns a bool value that indicates whether the particular relation is true or false. The operators with void return type always produce a compile-time error. Consequently, it is an error for one operand to be of type long and the other to be of type ulong.

Lifted (§14.2.7) forms of the unlifted predefined integer comparison operators defined above are also predefined.

14.9.2 Floating-point comparison operators

The predefined floating-point comparison operators are:

bool operator ==(float x, float y);
bool operator ==(double x, double y);
bool operator !=(float x, float y);
bool operator !=(double x, double y);
bool operator <(float x, float y);
bool operator <(double x, double y);
bool operator >(float x, float y);
bool operator >(double x, double y);
bool operator <=(float x, float y);
bool operator <=(double x, double y);
bool operator >=(float x, float y);
bool operator >=(double x, double y);

The operators compare the operands according to the rules of the IEC 60559 standard:

If either operand is NaN, the result is false for all operators except !=, for which the result is true. For any two operands, x != y always produces the same result as !(x == y). However, when one or both operands are NaN, the <, >, <=, and => operators do not produce the same results as the logical negation of the opposite operator. [Example: If either of x and y is NaN, then x < y is false, but !(x >= y) is true. end example]

- When neither operand is NaN, the operators compare the values of the two floating-point operands with respect to the ordering

  \(-\infty < -\max < \ldots < -\min < -0.0 == +0.0 < +\min < \ldots < +\max < +\infty\)

  where min and max are the smallest and largest positive finite values that can be represented in the given floating-point format. Notable effects of this ordering are:

  - Negative and positive zeros are considered equal.
  - A negative infinity is considered less than all other values, but equal to another negative infinity.
  - A positive infinity is considered greater than all other values, but equal to another positive infinity.

Lifted (§14.2.7) forms of the unlifted predefined floating-point comparison operators defined above are also predefined.
14.9.3 Decimal comparison operators
The predefined decimal comparison operators are:

```csharp
bool operator ==(decimal x, decimal y);
bool operator !=(decimal x, decimal y);
bool operator <(decimal x, decimal y);
bool operator >(decimal x, decimal y);
bool operator <=(decimal x, decimal y);
bool operator >=(decimal x, decimal y);
```

Each of these operators compares the numeric values of the two decimal operands and returns a `bool` value that indicates whether the particular relation is `true` or `false`. Each decimal comparison is equivalent to using the corresponding relational or equality operator of type `System.Decimal`.

Lifted (§14.2.7) forms of the unlifted predefined decimal comparison operators defined above are also predefined.

14.9.4 Boolean equality operators
The predefined Boolean equality operators are:

```csharp
bool operator ==(bool x, bool y);
bool operator !=(bool x, bool y);
```

The result of `==` is `true` if both `x` and `y` are `true` or if both `x` and `y` are `false`. Otherwise, the result is `false`.

The result of `!=` is `false` if both `x` and `y` are `true` or if both `x` and `y` are `false`. Otherwise, the result is `true`. When the operands are of type `bool`, the `!=` operator produces the same result as the `^` operator.

Lifted (§14.2.7) forms of the unlifted predefined Boolean equality operators defined above are also predefined.

14.9.5 Enumeration comparison operators
Every enumeration type implicitly provides the following predefined comparison operators:

```csharp
bool operator ==(E x, E y);
bool operator !=(E x, E y);
bool operator <(E x, E y);
bool operator >(E x, E y);
bool operator <=(E x, E y);
bool operator >=(E x, E y);
```

The result of evaluating `x op y`, where `x` and `y` are expressions of an enumeration type `E` with an underlying type `U`, and `op` is one of the comparison operators, is exactly the same as evaluating `((U)x) op ((U)y)`. In other words, the enumeration type comparison operators simply compare the underlying integral values of the two operands. These operators are only considered by overload resolution (§14.2.4) when one of the actual operands is of type `E`.

Lifted (§14.2.7) forms of the unlifted predefined enumeration comparison operators defined above are also predefined.

14.9.6 Reference type equality operators
Every class type `C` implicitly provides the following predefined reference type equality operators:

```csharp
bool operator ==(C x, C y);
bool operator !=(C x, C y);
```

unless predefined equality operators otherwise exists for `C` (for example, when `C` is `string` or `System.Delegate`).

The operators return the result of comparing the two references for equality or non-equality.
There are special rules for determining when a reference type equality operator is applicable. For an equality-expression with operands of type \( A \) and \( B \), define \( A_0 \) as follows:

- If \( A \) is a type parameter known to be a reference type (§25.7), let \( A_0 \) be the effective base class of \( A \).
- Otherwise, if \( A \) is an interface type, a delegate type, an array type, a class type, or the null type (§11.2.7), let \( A_0 \) be the same as \( A \).
- Otherwise, no reference type equality operator is applicable.

Now define \( A_1 \) as follows:

- If \( A_0 \) is an interface type, a delegate type, System.Delegate, or string, let \( A_1 \) be object.
- Otherwise, if \( A_0 \) is an array type, let \( A_1 \) be System.Array.
- Otherwise, \( A_0 \) is the null type or a class type and let \( A_1 \) be the same as \( A_0 \).

Define \( B_0 \) and \( B_1 \) in the same manner. Now determine if any reference type equality operators are applicable as follows:

- If both of the types \( A \) and \( B \) are the null type, then overload resolution is not performed and the result is a constant true or false, as specified in §14.9.
- Otherwise, if there is no identity or reference conversion (implicit or explicit) from \( A_0 \) to \( B_0 \) or no identity or reference conversion (implicit or explicit) from \( B_0 \) to \( A_0 \), then no reference type equality operator is applicable.
- Otherwise, if there is an identity or implicit reference conversion from \( A_1 \) to \( B_1 \), then the reference type equality operator for \( B_1 \) is applicable.
- Otherwise, if there is an implicit reference conversion from \( B_1 \) to \( A_1 \), then the reference type equality operator for \( A_1 \) is applicable.
- Otherwise no reference type equality operator is applicable.

[Note: Notable implications of these rules are:

- The predefined reference type equality operators cannot be used to compare two references that are known to be different at compile-time. [Example: If the compile-time types of the operands are two class types \( A \) and \( B \), and if neither \( A \) nor \( B \) derives from the other, then it would be impossible for the two operands to reference the same object and no reference type equality operator is applicable. Similarly, if \( A \) is a sealed class and \( B \) is an interface that \( A \) does not implement, then no reference type equality operator is applicable. end example]

- The predefined reference type equality operators do not permit value type operands to be compared.
- The predefined reference type equality operators never cause boxing operations to occur for their operands. It would be meaningless to perform such boxing operations, since references to the newly allocated boxed instances would necessarily differ from all other references.

end note]

When the operator overload resolution (§14.2.4) rules would pick an equality operator other than a reference type equality operator, selection of a reference type equality operator can be forced by explicitly casting one or both operands to type object. [Example: The example

using System;
```csharp
class Test
{
    static void Main()
    {
        string s = "Test";
        string t = string.Copy(s);
        Console.WriteLine(s == t);
        Console.WriteLine((object)s == t);
        Console.WriteLine(s == (object)t);
        Console.WriteLine((object)s == (object)t);
    }
}
```

produces the output

```
True
False
False
False
```

The `s` and `t` variables refer to two distinct `string` instances containing the same characters. The first comparison outputs `True` because the predefined string equality operator (§14.9.7) is selected when both operands are of type `string`. The remaining comparisons all output `False` because a predefined reference type equality operator is selected when one or both of the operands are of type `object`.

Note that the above technique is not meaningful for value types. The example

```csharp
class Test
{
    static void Main()
    {
        int i = 123;
        int j = 123;
        System.Console.WriteLine((object)i == (object)j);
    }
}
```

outputs `False` because the casts create references to two separate instances of boxed `int` values.

### 14.9.7 String equality operators

The predefined string equality operators are:

```csharp
bool operator ==(string x, string y);
bool operator !=(string x, string y);
```

Two `string` values are considered equal when one of the following is true:

- Both values are `null`.
- Both values are non-null references to string instances that have identical lengths and identical characters in each character position.

The string equality operators compare string values rather than string references. When two separate string instances contain the exact same sequence of characters, the values of the strings are equal, but the references are different. [Note: As described in §14.9.6, the reference type equality operators can be used to compare string references instead of string values. end note]

### 14.9.8 Delegate equality operators

Every delegate type implicitly provides the following predefined comparison operators, where `D` is the delegate type:

```csharp
bool operator ==(D x, D y);
bool operator !=(D x, D y);
```

These operators are only considered by overload resolution (§14.2.4) when one of the actual operands is of type `D`. 

208
The following predefined operators are available for comparing delegates when the delegate type is not known at compile time:

```csharp
bool operator ==(System.Delegate x, System.Delegate y);
bool operator !=(System.Delegate x, System.Delegate y);
```

These latter operators are not considered applicable if the types of the operands are distinct delegate types. [Example:

```csharp
delegate void D();
delegate void E();
static bool Compare1(D d, E e) {
    return d == e;  // Error
}
static bool Compare2(System.Delegate d, E e) {
    return d == e;  // Ok
}
```

The comparison in `Compare1` produces an error since the types of the operands are distinct delegate types. In this case, none of the delegate equality operators or reference equality operators is applicable since a non-null instance of `D` could never be equal to an instance of `E`. end example]

Two delegate instances are considered equal as follows:

- If either of the delegate instances is `null`, they are equal if and only if both are `null`.
- If the delegate instances have different runtime types, they are not equal.
- If both of the delegate instances have an invocation list (§22.1), those instances are equal if and only if their invocation lists are the same length, and each entry in one’s invocation list is equal (as defined below) to the corresponding entry, in order, in the other’s invocation list.

The following rules govern the equality of invocation list entries:

- If two invocation list entries both refer to the same static method then the entries are equal.
- If two invocation list entries both refer to the same non-static method on the same target object (as defined by the reference equality operators) then the entries are equal.
- Invocation list entries produced from evaluation of semantically identical `anonymous-method-expressions` with the same (possibly empty) set of captured outer variable instances are permitted (but not required) to be equal.
- Invocation list entries produced from evaluation of semantically different `anonymous-method-expressions` or having different sets of captured outer variable instances are never equal.
- An invocation list entry produced from evaluation of an `anonymous-method-expression` is never equal to an invocation list entry produced from a `delegate-creation-expression` on a method group.

### 14.9.9 Equality operators and null

The `==` and `!=` operators permit one operand to be a value of a nullable type and the other to have the `null` type (§11.2.7), even if no predefined or user-defined operator (in unlifted or lifted form) exists for the operation.

For an operation of one of the forms

```csharp
x == null  null == x  x != null  null != x
```

where `x` is an expression of a nullable type, if operator overload resolution (§14.2.4) fails to find an applicable operator, the result is instead computed from the `HasValue` property of `x`. Specifically, the first two forms are translated into `!x.HasValue`, and last two forms are translated into `x.HasValue`. 

209
14.9.10 is operator

The `is` operator is used to dynamically check if the run-time type of an object is compatible with a given type. The result of the operation `e is T`, where `e` is an expression and `T` is a type, is a Boolean value indicating whether `e` can successfully be converted to type `T` by a reference conversion, a boxing conversion, or an unboxing conversion. The operation is evaluated as follows:

- If the compile-time type of `e` is the same as `T`, or if an implicit reference conversion (§13.1.4) or boxing conversion (§13.1.5) exists from the compile-time type of `e` to `T`:
  - If `e` is of a reference type, the result of the operation is equivalent to evaluating `e != null`.
  - If `e` is of a value type, the result of the operation is `true`.

- Otherwise, if an explicit reference conversion (§13.2.3) or unboxing conversion (§13.2.4) exists from the compile-time type of `e` to `T`, a dynamic type check is performed:
  - If the value of `e` is `null`, the result is `false`.
  - Otherwise, let `R` be the run-time type of the instance referenced by `e`. If `R` and `T` are the same type, if `R` is a reference type and an implicit reference conversion from `R` to `T` exists, or if `R` is a value type and `T` is an interface type that is implemented by `R`, the result is `true`.
  - Otherwise, the result is `false`.

- Otherwise, if the compile-time type of `e` or `T` is an open type (§25.5.2), a dynamic type check is performed.

- Otherwise, no reference or boxing conversion of `e` to type `T` is possible, and the result of the operation is `false`.

The `is` operator only considers reference conversions, boxing conversions, and unboxing conversions. Other conversions, such as user defined conversions, are not considered by the `is` operator.

14.9.11 as operator

The `as` operator is used to explicitly convert a value to a given reference type using a reference conversion or a boxing conversion. Unlike a cast expression (§14.6.6), the `as` operator never throws an exception. Instead, if the indicated conversion is not possible, the resulting value is `null`.

In an operation of the form `e as T`, `e` shall be an expression and `T` shall be a reference type or a type parameter that is known to be a reference type (§25.7). The type of the result is `T`, and the result is always classified as a value. The operation is evaluated as follows:

- If the compile-time type of `e` is the same as `T`, the result is simply the value of `e`.

- Otherwise, if an implicit reference conversion (§13.1.4) or boxing conversion (§13.1.5) exists from the compile-time type of `e` to `T`, this conversion is performed and becomes the result of the operation.

- Otherwise, if an explicit reference conversion (§13.2.3) exists from the compile-time type of `e` to `T`, a dynamic type check is performed:
  - If the value of `e` is `null`, the result is the value `null` with the compile-time type `T`.
  - Otherwise, let `R` be the run-time type of the instance referenced by `e`. If `R` and `T` are the same type, if `R` is a reference type and an implicit reference conversion from `R` to `T` exists, or if `R` is a value type and `T` is an interface type that is implemented by `R`, the result is the reference given by `e` with the compile-time type `T`.
  - Otherwise, the result is the value `null` with the compile-time type `T`.

- Otherwise, if the compile-time type of `e` or `T` is an open type (§25.5.2), a dynamic type check is performed.

- Otherwise, the indicated conversion is never possible, and a compile-time error occurs.
The `as` operator only performs reference conversions and boxing conversions. Other conversions, such as user defined conversions, are not possible with the `as` operator and should instead be performed using cast expressions.

The `as` operator can be used with a type parameter `T` (§25.1.1) as the right-hand side only if `T` is known to be a reference type (§25.7). This restriction is required because the value `null` might be returned as a result of the operator. [Example:

```
class X
{
    public T F<T>(object o) where T: Attribute {
        return o as T;    // Ok, T has a class type constraint
    }
    public T G<T>(object o) {
        return o as T;    // Error, unconstrained T
    }
}
```

end example]

[Note: When constraints are factored in, there are situations where the compiler can conclude that the operation `e as T` will never succeed, for example, when `e` is a struct or sealed class that doesn’t implement a particular interface, and `T` is constrained to require that interface. However, a complete specification of those situations is complicated, and the rules given above seem to be the best compromise. end note]

### 14.10 Logical operators

The `&`, `^`, and `|` operators are called the logical operators.

- **and-expression:**
  
  
  equality-expression
  
  and-expression & equality-expression

- **exclusive-or-expression:**
  
  and-expression
  
  exclusive-or-expression ^ and-expression

- **inclusive-or-expression:**
  
  exclusive-or-expression
  
  inclusive-or-expression | exclusive-or-expression

For an operation of the form `x op y`, where `op` is one of the logical operators, overload resolution (§14.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined logical operators are described in the following subclauses.

### 14.10.1 Integer logical operators

The predefined integer logical operators are:

```
int operator &(int x, int y);
uint operator &(uint x, uint y);
long operator &(long x, long y);
ulong operator &(ulong x, ulong y);
void operator &(long x, ulong y);
void operator &(ulong x, long y);
int operator |(int x, int y);
uint operator |(uint x, uint y);
long operator |(long x, long y);
ulong operator |(ulong x, ulong y);
void operator |(long x, ulong y);
void operator |(ulong x, long y);
```
The & operator computes the bitwise logical AND of the two operands, the | operator computes the bitwise logical OR of the two operands, and the ^ operator computes the bitwise logical exclusive OR of the two operands. No overflows are possible from these operations. The operators with void return type always produce a compile-time error. Consequently, it is an error for one operand to be of type long and the other to be of type ulong.

Lifted (§14.2.7) forms of the unlifted predefined integer logical operators defined above are also predefined.

### 14.10.2 Enumeration logical operators

Every enumeration type $E$ implicitly provides the following predefined logical operators:

- $E$ operator &(E x, E y);
- $E$ operator |(E x, E y);
- $E$ operator ^(E x, E y);

The result of evaluating $x$ op $y$, where $x$ and $y$ are expressions of an enumeration type $E$ with an underlying type $U$, and op is one of the logical operators, is exactly the same as evaluating (E)((U)x op (U)y). In other words, the enumeration type logical operators simply perform the logical operation on the underlying type of the two operands. These operators are only considered by overload resolution (§14.2.4) when one of the actual operands is of type $E$.

Lifted (§14.2.7) forms of the unlifted predefined enumeration logical operators defined above are also predefined.

### 14.10.3 Boolean logical operators

The predefined Boolean logical operators are:

- bool operator &(bool x, bool y);
- bool operator |(bool x, bool y);
- bool operator ^(bool x, bool y);

The result of $x$ & $y$ is true if both $x$ and $y$ are true. Otherwise, the result is false.

The result of $x$ | $y$ is true if either $x$ or $y$ is true. Otherwise, the result is false.

The result of $x$ ^ $y$ is true if $x$ is true and $y$ is false, or $x$ is false and $y$ is true. Otherwise, the result is false. When the operands are of type bool, the ^ operator computes the same result as the != operator.

### 14.10.4 The bool? logical operators

The nullable Boolean type bool? can represent three values, true, false, and null, and is conceptually similar to the three-valued type used for Boolean expressions in SQL. To ensure that the results produced by the & and | operators for bool? operands are consistent with SQL’s three-valued logic, the following predefined operators are provided:

- bool? operator &(bool? x, bool? y);
- bool? operator |(bool? x, bool? y);

The following table lists the results produced by these operators for all combinations of the values true, false, and null:
The `bool?` type is considered to implement operator `true` and operator `false` in the obvious manner: operator `true` returns `true` if the operand is `true`, and operator `false` returns `true` if the operand is `false`.

Because `bool?` implements these operators, operands of the `&&` and `||` operators are permitted to be of type `bool?` (§14.11.2), the first operand of the `?:` operator is permitted to be of type `bool?` (§14.13), and expressions of type `bool?` can be used with `if`, `while`, `do`, and `for` statements (§14.17).

### 14.11 Conditional logical operators

The `&&` and `||` operators are called the conditional logical operators. They are also called the “short-circuiting” logical operators.

```
conditional-and-expression:
  conditional-and-expression & inclusive-or-expression
conditional-or-expression:
  conditional-and-expression || conditional-and-expression
```

The `&&` and `||` operators are conditional versions of the `&` and `|` operators:

- The operation `x && y` corresponds to the operation `x & y`, except that `y` is evaluated only if `x` is `true`.
- The operation `x || y` corresponds to the operation `x | y`, except that `y` is evaluated only if `x` is `false`.

An operation of the form `x && y` or `x || y` is processed by applying overload resolution (§14.2.4) as if the operation was written `x & y` or `x | y`. Then,

- If overload resolution fails to find a single best operator, or if overload resolution selects one of the predefined integer logical operators, a compile-time error occurs.
- Otherwise, if the selected operator is one of the predefined Boolean logical operators (§14.10.2), the operation is processed as described in §14.11.1.
- Otherwise, the selected operator is a user-defined operator, and the operation is processed as described in §14.11.2.

It is not possible to directly overload the conditional logical operators. However, because the conditional logical operators are evaluated in terms of the regular logical operators, overloads of the regular logical operators are, with certain restrictions, also considered overloads of the conditional logical operators. This is described further in §14.11.2.
14.11.1 Boolean conditional logical operators
When overload resolution (§14.2.4) for x & y or x | y selects the predefined Boolean & or | operator, then x && y or x || y is processed as follows:

- The operation x && y is evaluated as (bool)x ? (bool)y : false. In other words, x is first evaluated and converted to type bool. Then, if x is true, y is evaluated and converted to type bool, and this becomes the result of the operation. Otherwise, the result of the operation is false.

- The operation x || y is evaluated as (bool)x ? true : (bool)y. In other words, x is first evaluated and converted to type bool. Then, if x is true, the result of the operation is true. Otherwise, y is evaluated and converted to type bool, and this becomes the result of the operation.

14.11.2 User-defined conditional logical operators
When overload resolution (§14.2.4) for x & y or x | y selects a user defined & or | operator, then processing x && y or x || y requires that both of the following shall be true, where T is the type in which the selected operator is declared:

- The return type and the type of each parameter of the selected operator shall be T. In other words, the operator shall compute the logical AND or the logical OR of two operands of type T, and shall return a result of type T.

- T shall contain declarations of operator true and operator false.

A compile-time error occurs if either of these requirements is not satisfied. Otherwise, the && or || operation is evaluated by combining the user-defined operator true or operator false with the selected user-defined operator:

- The operation x && y is evaluated as T.false((T)x) ? (T)x : T.&((T)x, y), where T.false((T)x) is an invocation of the operator false declared in T, and T.&((T)x, y) is an invocation of the selected operator &. In addition, the value (T)x shall only be evaluated once. In other words, x is first evaluated and converted to type T and operator false is invoked on the result to determine if x is definitely false. Then, if x is definitely false, the result of the operation is the value previously computed for x converted to type T. Otherwise, y is evaluated, and the selected operator & is invoked on the value previously computed for x converted to type T and the value computed for y to produce the result of the operation.

- The operation x || y is evaluated as T.true((T)x) ? (T)x : T.|((T)x, y), where T.true((T)x) is an invocation of the operator true declared in T, and T.|((T)x, y) is an invocation of the selected operator |. In addition, the value (T)x shall only be evaluated once. In other words, x is first evaluated and converted to type T and operator true is invoked on the result to determine if x is definitely true. Then, if x is definitely true, the result of the operation is the value previously computed for x converted to type T. Otherwise, y is evaluated, and the selected operator | is invoked on the value previously computed for x converted to type T and the value computed for y to produce the result of the operation.

In either of these operations, the expression given by x is only evaluated once, and the expression given by y is either not evaluated or evaluated exactly once. [Note: The bool? type is considered to implement operator true and operator false in the obvious manner. Expressions of type bool? can be used as the operands of conditional logical operator. end note]

For an example of a type that implements operator true and operator false, see §Error! Reference source not found..

14.12 The null coalescing operator
The ?? operator is called the null coalescing operator.
A null coalescing expression of the form `a ?? b` requires `a` to be of a nullable type or reference type. If `a` is non-null, the result of `a ?? b` is `a`; otherwise, the result is `b`. The operation evaluates `b` only if `a` is null.

The null coalescing operator is right-associative, meaning that operations are grouped from right to left. [Example: An expression of the form `a ?? b ?? c` is evaluated as `a ?? (b ?? c)`. In general terms, an expression of the form `E1 ?? E2 ?? ... ?? EN` returns the first of the operands that is non-null, or null if all operands are null. end example]

The type of the expression `a ?? b` depends on which implicit conversions are available between the types of the operands. In order of preference, the type of `a ?? b` is `A0`, `A`, or `B`, where `A` is the type of `a`, `B` is the type of `b`, and `A0` is the type that results from removing the trailing `?` modifier, if any, from `A`. Specifically, `a ?? b` is processed as follows:

- If `A` is not a nullable type or a reference type, a compile-time error occurs.
- If `A` is a nullable type and an implicit conversion exists from `b` to `A0`, the result type is `A0`. At run-time, `a` is first evaluated. If `a` is not null, `a` is unwrapped to type `A0`, and this becomes the result. Otherwise, `b` is evaluated and converted to type `A0`, and this becomes the result.
- Otherwise, if an implicit conversion exists from `b` to `A`, the result type is `A`. At run-time, `a` is first evaluated. If `a` is not null, `a` becomes the result. Otherwise, `b` is evaluated and converted to type `A`, and this becomes the result.
- Otherwise, if an implicit conversion exists from `A0` to `B`, the result type is `B`. At run-time, `a` is first evaluated. If `a` is not null, `a` is unwrapped to type `A0` (unless `A` and `A0` are the same type) and converted to type `B`, and this becomes the result. Otherwise, `b` is evaluated and becomes the result.

Otherwise, `a` and `b` are incompatible, and a compile-time error occurs.

### 14.13 Conditional operator

The `?:` operator is called the conditional operator. It is at times also called the ternary operator.

A conditional expression of the form `b ? x : y` first evaluates the condition `b`. Then, if `b` is `true`, `x` is evaluated and becomes the result of the operation. Otherwise, `y` is evaluated and becomes the result of the operation. A conditional expression never evaluates both `x` and `y`.

The conditional operator is right-associative, meaning that operations are grouped from right to left. [Example: An expression of the form `a ? b : c ? d : e` is evaluated as `a ? b : (c ? d : e)`. end example]

The first operand of the `?:` operator shall be an expression of a type that can be implicitly converted to `bool`, or an expression of a type that implements operator `true`. If neither of these requirements is satisfied, a compile-time error occurs. [Note: The `bool?` type is considered to implement operator `true` and operator `false` in the obvious manner. Expressions of type `bool?` can be used as the first operand of a `?:` expression. end note]

The second and third operands of the `?:` operator control the type of the conditional expression. Let `X` and `Y` be the types of the second and third operands. Then,

- If `X` and `Y` are the same type, then this is the type of the conditional expression.
- Otherwise, if an implicit conversion (§13.1) exists from `X` to `Y`, but not from `Y` to `X`, then `Y` is the type of the conditional expression.
• Otherwise, if an implicit conversion (§13.1) exists from Y to X, but not from X to Y, then X is the type of the conditional expression.

• Otherwise, no expression type can be determined, and a compile-time error occurs.

The run-time processing of a conditional expression of the form b ? x : y consists of the following steps:

• First, b is evaluated, and the bool value of b is determined:
  o If an implicit conversion from the type of b to bool exists, then this implicit conversion is performed to produce a bool value.
  o Otherwise, the operator true defined by the type of b is invoked to produce a bool value.

• If the bool value produced by the step above is true, then x is evaluated and converted to the type of the conditional expression, and this becomes the result of the conditional expression.

• Otherwise, y is evaluated and converted to the type of the conditional expression, and this becomes the result of the conditional expression.

14.14 Assignment operators

The assignment operators assign a new value to a variable, a property, event, or an indexer element.

\[
\text{assignment: } \quad \text{unary-expression} \quad \text{assignment-operator} \quad \text{expression}
\]

\[
\text{assignment-operator: one of } \quad = \quad += \quad -= \quad *= \quad /= \quad %= \quad &= \quad |= \quad ^= \quad >>= \quad \text{right-shift-assignment}
\]

The left operand of an assignment shall be an expression classified as a variable, a property access, an indexer access, or an event access.

The = operator is called the simple assignment operator. It assigns the value of the right operand to the variable, property, or indexer element given by the left operand. The left operand of the simple assignment operator shall not be an event access (except as described in §17.7.1). The simple assignment operator is described in §14.14.1.

The operators formed by prefixing an = character with a binary operator are called the compound assignment operators. These operators perform the indicated operation on the two operands, and then assign the resulting value to the variable, property, or indexer element given by the left operand. The compound assignment operators are described in §14.14.2.

The += and -= operators with an event access expression as the left operand are called the event assignment operators. No other assignment operator is valid with an event access as the left operand. The event assignment operators are described in §14.13.3.

The assignment operators are right-associative, meaning that operations are grouped from right to left. [Example: An expression of the form a = b = c is evaluated as a = (b = c). end example]

14.14.1 Simple assignment

The = operator is called the simple assignment operator. In a simple assignment, the right operand shall be an expression of a type that is implicitly convertible to the type of the left operand. The operation assigns the value of the right operand to the variable, property, or indexer element given by the left operand.

The result of a simple assignment expression is the value assigned to the left operand. The result has the same type as the left operand, and is always classified as a value.

If the left operand is a property or indexer access, the property or indexer shall have a set accessor. If this is not the case, a compile-time error occurs.

The run-time processing of a simple assignment of the form x = y consists of the following steps:

• If x is classified as a variable:
• x is evaluated to produce the variable.
• y is evaluated and, if required, converted to the type of x through an implicit conversion (§13.1).
• If the variable given by x is an array element of a reference-type, a run-time check is performed to ensure that the value computed for y is compatible with the array instance of which x is an element. The check succeeds if y is null, or if an implicit reference conversion (§13.1.4) exists from the runtime type of the instance referenced by y to the actual element type of the array instance containing x. Otherwise, a System.ArrayTypeMismatchException is thrown.
• The value resulting from the evaluation and conversion of y is stored into the location given by the evaluation of x.

If x is classified as a property or indexer access:
• The instance expression (if x is not static) and the argument list (if x is an indexer access) associated with x are evaluated, and the results are used in the subsequent set accessor invocation.
• y is evaluated and, if required, converted to the type of x through an implicit conversion (§13.1).
• The set accessor of x is invoked with the value computed for y as its value argument.

[Note: The array covariance rules (§19.5) permit a value of an array type A[] to be a reference to an instance of an array type B[], provided an implicit reference conversion exists from B to A. Because of these rules, assignment to an array element of a reference-type requires a run-time check to ensure that the value being assigned is compatible with the array instance. In the example

```java
string[] sa = new string[10];
object[] oa = sa;
oa[0] = null; // Ok
oa[1] = "Hello"; // Ok
oa[2] = new ArrayList(); // ArrayTypeMismatchException
```
the last assignment causes a System.ArrayTypeMismatchException to be thrown because an instance of ArrayList cannot be stored in an element of a string[]. end note]

When a property or indexer declared in a struct-type is the target of an assignment, the instance expression associated with the property or indexer access shall be classified as a variable. If the instance expression is classified as a value, a compile-time error occurs. [Note: Because of §14.5.4, the same rule also applies to fields. end note]

[Example: Given the declarations:

```java
struct Point
{
    int x, y;
    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
    public int x {
        get { return x; }
        set { x = value; }
    }
    public int y {
        get { return y; }
        set { y = value; }
    }
}
struct Rectangle
{
    Point a, b;
}
```
public Rectangle(Point a, Point b) {
    this.a = a;
    this.b = b;
}

public Point A {
    get { return a; }
    set { a = value; }
}

public Point B {
    get { return b; }
    set { b = value; }
}

in the example

Point p = new Point();
p.X = 100;
p.Y = 100;
Rectangle r = new Rectangle();
r.A = new Point(10, 10);
r.B = p;

the assignments to p.X, p.Y, r.A, and r.B are permitted because p and r are variables. However, in the example

Rectangle r = new Rectangle();
r.A.X = 10;
r.A.Y = 10;
r.B.X = 100;
r.B.Y = 100;

the assignments are all invalid, since r.A and r.B are not variables. end example]

14.14.2 Compound assignment

An operation of the form x op= y is processed by applying binary operator overload resolution (§14.2.4) as if the operation was written x op y. Then,

- If the return type of the selected operator is implicitly convertible to the type of x, the operation is evaluated as x = x op y, except that x is evaluated only once.
- Otherwise, if the selected operator is a predefined operator, if the return type of the selected operator is explicitly convertible to the type of x, and if y is implicitly convertible to the type of x or the operator is a shift operator, then the operation is evaluated as x = (T)(x op y), where T is the type of x, except that x is evaluated only once.
- Otherwise, the compound assignment is invalid, and a compile-time error occurs.

The term “evaluated only once” means that in the evaluation of x op y, the results of any constituent expressions of x are temporarily saved and then reused when performing the assignment to x. [Example: In the assignment A[0][B[0]] += C, where A is a method returning int[], and B and C are methods returning int, the methods are invoked only once, in the order A, B, C. end example]

When the left operand of a compound assignment is a property access or indexer access, the property or indexer shall have both a get accessor and a set accessor. If this is not the case, a compile-time error occurs.

The second rule above permits x op= y to be evaluated as x = (T)(x op y) in certain contexts. The rule exists such that the predefined operators can be used as compound operators when the left operand is of type sbyte, byte, short, ushort, or char. Even when both arguments are of one of those types, the predefined operators produce a result of type int, as described in §14.2.6.2. Thus, without a cast it would not be possible to assign the result to the left operand.
The intuitive effect of the rule for predefined operators is simply that \( x \ op \ y \) is permitted if both of \( x \ op \ y \) and \( x = y \) are permitted. [Example: In the following code

```c
byte b = 0;
char ch = '\0';
int i = 0;
b += 1;     // Ok
b += 1000;   // Error, b = 1000 not permitted
b += 1;     // Error, b = i not permitted
b += (byte)i;     // Ok
ch += 1;    // Error, ch = 1 not permitted
ch += (char)1; // Ok
```
the intuitive reason for each error is that a corresponding simple assignment would also have been an error.  
end example]

[Note: Compound assignment operations support lifted operators. Since a compound assignment \( x \ op \ y \) is evaluated as either \( x = x \ op y \) or \( x = (T)(x \ op y) \), the rules of evaluation implicitly cover lifted operators. end note]

### 14.14.3 Event assignment
If the left operand of a `+=` or `-=` removes a handler for the event. The example operator is classified as an event access, and then the expression is evaluated as follows:

- The instance expression, if any, of the event access is evaluated.
- The right operand of the `+=` or `-=` operator is evaluated, and, if required, converted to the type of the left operand through an implicit conversion (§13.1).
- An event accessor of the event is invoked, with argument list consisting of the value computed in the previous step. If the operator was `+=`, the `add` accessor is invoked; if the operator was `-=`, the `remove` accessor is invoked.

An event assignment expression does not yield a value. Thus, an event assignment expression is valid only in the context of a `statement-expression` (§15.6).

### 14.15 Expression
An expression is either a `conditional-expression` or an `assignment`.

```c
expression:
  conditional-expression
  assignment
```

### 14.16 Constant expressions
A `constant-expression` is an expression that can be fully evaluated at compile-time.

```c
constant-expression:
  expression
```

The type of a constant expression can be one of the following: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `string`, any enumeration type, or the null type (§11.2.7). The following constructs are permitted in constant expressions:

- Literals (including the `null` literal)
- References to `const` members of class and struct types.
- References to members of enumeration types.
- Parenthesized sub-expressions, which are themselves constant expressions.
- Cast expressions, provided the target type is one of the types listed above.
The predefined `+`, `-`, `!`, and `~` unary operators.

The predefined `+`, `-`, `*`, `/`, `<`, `>`, `<=`, and `>=` binary operators, provided each operand is of a type listed above.

The `?:` conditional operator.

`sizeof` expressions, provided the unmanaged-type is one of the types specified in §14.5.12

Whenever an expression is of one of the types listed above and contains only the constructs listed above, the expression is evaluated at compile-time. This is true even if the expression is a sub-expression of a larger expression that contains non-constant constructs.

The compile-time evaluation of constant expressions uses the same rules as run-time evaluation of non-constant expressions, except that where run-time evaluation would have thrown an exception, compile-time evaluation causes a compile-time error to occur.

Unless a constant expression is explicitly placed in an `unchecked` context, overflows that occur in integral-type arithmetic operations and conversions during the compile-time evaluation of the expression always cause compile-time errors (§14.5.12).

Constant expressions occur in the contexts listed below. In these contexts, a compile-time error occurs if an expression cannot be fully evaluated at compile-time.

- Constant declarations (§17.3)
- Enumeration member declarations (§21.30)
- `case` labels of a `switch` statement (§15.7.2).
- `goto` `case` statements (§15.9.3)
- Dimension lengths in an array creation expression (§14.5.10.2) that includes an initializer.
- Attributes (§24)

An implicit constant expression conversion (§13.1.7) permits a constant expression of type `int` to be converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, or `ulong`, provided the value of the constant expression is within the range of the destination type.

### 14.17 Boolean expressions

A `boolean-expression` is an expression that yields a result of type `bool`.

```plaintext
boolean-expression:
expression
```

The controlling conditional expression of an `if-statement` (§15.7.1), `while-statement` (§15.8.1), `do-statement` (§15.8.2), or `for-statement` (§15.8.3) is a `boolean-expression`. The controlling conditional expression of the `?:` operator (§14.13) follows the same rules as a `boolean-expression`, but for reasons of operator precedence is classified as a `null-coalescing-expression`.

A `boolean-expression` is required to be of a type that can be implicitly converted to `bool` or of a type that implements `operator true`. [Note: As required by §17.9.1, any type that implements `operator true` shall also implement `operator false`. end note] If neither requirement is satisfied, a compile-time error occurs.

When a Boolean expression is of a type that cannot be implicitly converted to `bool` but does implement `operator true`, then following evaluation of the expression, the `operator true` implementation provided by that type is invoked to produce a `bool` value. [Note: The `bool?` type is considered to implement `operator true` and `operator false` in the obvious manner. Expressions of type `bool?` can be used as a `boolean-expression`. end note]

[Note: The `DBBool` struct type in §Error! Reference source not found. provides an example of a type that implements `operator true` and `operator false`. end note]
15. Statements

C# provides a variety of statements. [Note: Most of these statements will be familiar to developers who have programmed in C and C++. end note]

statement:
  labeled-statement
  declaration-statement
  embedded-statement

embedded-statement:
  block
  empty-statement
  expression-statement
  selection-statement
  iteration-statement
  jump-statement
  try-statement
  checked-statement
  unchecked-statement
  lock-statement
  using-statement
  yield-statement

The embedded-statement non-terminal is used for statements that appear within other statements. The use of embedded-statement rather than statement excludes the use of declaration statements and labeled statements in these contexts. [Example: The code

```csharp
void F(bool b) {
    if (b)
        int i = 44;
}
```

results in a compile-time error because an if statement requires an embedded-statement rather than a statement for its if branch. If this code were permitted, then the variable i would be declared, but it could never be used. (Note, however, that by placing i’s declaration in a block, the example is valid.) end example]

15.1 End points and reachability

Every statement has an end point. In intuitive terms, the end point of a statement is the location that immediately follows the statement. The execution rules for composite statements (statements that contain embedded statements) specify the action that is taken when control reaches the end point of an embedded statement. [Example: When control reaches the end point of a statement in a block, control is transferred to the next statement in the block. end example]

If a statement can possibly be reached by execution, the statement is said to be reachable. Conversely, if there is no possibility that a statement will be executed, the statement is said to be unreachable. [Example: In the following code

```csharp
void F(bool b) {
    if (b)
        int i = 44;
    
    if (true)
        string s = null;
    
    if (false)
        int j = 55;
}
```
void F() {
    Console.WriteLine("reachable");
    goto Label;
    Console.WriteLine("unreachable");
    Label:
    Console.WriteLine("reachable");
}

the second invocation of Console.WriteLine is unreachable because there is no possibility that the statement will be executed. end example]

A warning is reported if the compiler determines that a statement is unreachable. It is specifically not an error for a statement to be unreachable.

[Note: To determine whether a particular statement or end point is reachable, the compiler performs flow analysis according to the reachability rules defined for each statement. The flow analysis takes into account the values of constant expressions (§14.16) that control the behavior of statements, but the possible values of non-constant expressions are not considered. In other words, for purposes of control flow analysis, a non-constant expression of a given type is considered to have any possible value of that type.

In the example

void F() {
    const int i = 1;
    if (i == 2) Console.WriteLine("unreachable");
}

the Boolean expression of the if statement is a constant expression because both operands of the == operator are constants. As the constant expression is evaluated at compile-time, producing the value false, the Console.WriteLine invocation is considered unreachable. However, if i is changed to be a local variable

void F() {
    int i = 1;
    if (i == 2) Console.WriteLine("reachable");
}

the Console.WriteLine invocation is considered reachable, even though, in reality, it will never be executed. end note]

The block of a function member is always considered reachable. The block of an anonymous-method-expression is always considered reachable. By successively evaluating the reachability rules of each statement in a block, the reachability of any given statement can be determined.

[Example: In the following code

void F(int x) {
    Console.WriteLine("start");
    if (x < 0) Console.WriteLine("negative");
}

the reachability of the second Console.WriteLine is determined as follows:

• The first Console.WriteLine expression statement is reachable because the block of the F method is reachable (§15.2).
• The end point of the first Console.WriteLine expression statement is reachable because that statement is reachable (§15.6 and §15.2).
• The if statement is reachable because the end point of the first Console.WriteLine expression statement is reachable (§15.6 and §15.2).
• The second Console.WriteLine expression statement is reachable because the Boolean expression of the if statement does not have the constant value false.

end example]

There are two situations in which it is a compile-time error for the end point of a statement to be reachable:
• Because the switch statement does not permit a switch section to “fall through” to the next switch section, it is a compile-time error for the end point of the statement list of a switch section to be reachable. If this error occurs, it is typically an indication that a break statement is missing.

• It is a compile-time error for the end point of the block of a function member that computes a value to be reachable. If this error occurs, it typically is an indication that a return statement is missing.

15.2 Blocks
A block permits multiple statements to be written in contexts where a single statement is allowed.

```
block:
    { statement-listopt }
```

A block consists of an optional statement-list (§15.2.1), enclosed in braces. If the statement list is omitted, the block is said to be empty.

A block can contain declaration statements (§15.5). The scope of a local variable or constant declared in a block is the block.

Within a block, the meaning of a name used in an expression or declarator context shall always be the same (§14.5.2.1).

A block is executed as follows:

• If the block is empty, control is transferred to the end point of the block.

• If the block is not empty, control is transferred to the statement list. When and if control reaches the end point of the statement list, control is transferred to the end point of the block.

The statement list of a block is reachable if the block itself is reachable.

The end point of a block is reachable if the block is empty or if the end point of the statement list is reachable.

15.2.1 Statement lists
A statement list consists of one or more statements written in sequence. Statement lists occur in blocks (§15.2) and in switch-blocks (§15.7.2).

```
statement-list:
    statement
    statement-list statement
```

A statement list is executed by transferring control to the first statement. When and if control reaches the end point of a statement, control is transferred to the next statement. When and if control reaches the end point of the last statement, control is transferred to the end point of the statement list.

A statement in a statement list is reachable if at least one of the following is true:

• The statement is the first statement and the statement list itself is reachable.

• The end point of the preceding statement is reachable.

• The statement is a labeled statement and the label is referenced by a reachable goto statement.

The end point of a statement list is reachable if the end point of the last statement in the list is reachable.

15.3 The empty statement
An empty-statement does nothing.

```
empty-statement:
    ;
```
An empty statement is used when there are no operations to perform in a context where a statement is required.

Execution of an empty statement simply transfers control to the end point of the statement. Thus, the end point of an empty statement is reachable if the empty statement is reachable.

[Example: An empty statement can be used when writing a `while` statement with a null body:

```c#
bool ProcessMessage() {...}
void ProcessMessages() {
    while (ProcessMessage())
    ;
}

Also, an empty statement can be used to declare a label just before the closing “)” of a block:

```c#
void F() {
    ...
    if (done) goto exit;
    ...
    exit: ;
}

end example]

15.4 Labeled statements

A labeled-statement permits a statement to be prefixed by a label. Labeled statements are permitted in blocks, but are not permitted as embedded statements.

```
labeled-statement:
    identifier : statement
```

A labeled statement declares a label with the name given by the `identifier`. The scope of a label is the whole block in which the label is declared, including any nested blocks. It is a compile-time error for two labels with the same name to have overlapping scopes.

A label can be referenced from `goto` statements (§15.9.3) within the scope of the label. [Note: This means that `goto` statements can transfer control within blocks and out of blocks, but never into blocks. end note]

Labels have their own declaration space and do not interfere with other identifiers. [Example: The example

```c#
int F(int x) {
    if (x >= 0) goto x;
    x = -x;
    x: return x;
}
```

is valid and uses the name `x` as both a parameter and a label. end example]

Execution of a labeled statement corresponds exactly to execution of the statement following the label.

In addition to the reachability provided by normal flow of control, a labeled statement is reachable if the label is referenced by a reachable `goto` statement, unless the `goto` statement is inside a `try` that includes a `finally` block whose end point is unreachable, and the labeled statement is outside the `try`.

15.5 Declaration statements

A declaration-statement declares a local variable or constant. Declaration statements are permitted in blocks, but are not permitted as embedded statements.

```
declaration-statement:
    local-variable-declaration ;
    local-constant-declaration ;
```
15.5.1 Local variable declarations

A \textit{local-variable-declaration} declares one or more local variables.

\begin{verbatim}
local-variable-declaration:
  type  local-variable-declarators

local-variable-declarators:
  local-variable-declarator
  local-variable-declarators ,  local-variable-declarator

local-variable-declarator:
  identifier
  identifier  =  local-variable-initializer

local-variable-initializer:
  expression
  array-initializer
\end{verbatim}

The \textit{type} of a \textit{local-variable-declaration} specifies the type of the variables introduced by the declaration. The type is followed by a list of \textit{local-variable-declarators}, each of which introduces a new variable. A \textit{local-variable-declarator} consists of an \textit{identifier} that names the variable, optionally followed by an \textquotedblright\textquoteleft\textquotedblright\ equals token and a \textit{local-variable-initializer} that gives the initial value of the variable.

The value of a local variable is obtained in an expression using a \textit{simple-name} (§14.5.2), and the value of a local variable is modified using an \textit{assignment} (§14.14). A local variable shall be definitely assigned (§12.3) at each location where its value is obtained.

The scope of a local variable declared in a \textit{local-variable-declaration} is the block in which the declaration occurs. It is an error to refer to a local variable in a textual position that precedes the \textit{local-variable-declarator} of the local variable. Within the scope of a local variable, it is a compile-time error to declare another local variable or constant with the same name.

A local variable declaration that declares multiple variables is equivalent to multiple declarations of single variables with the same type. Furthermore, a variable initializer in a local variable declaration corresponds exactly to an assignment statement that is inserted immediately after the declaration.

\begin{example}
\begin{verbatim}
void F() {
  int x = 1, y, z = x * 2;
}
\end{verbatim}
\end{example}

\textit{Example: The example}

\begin{verbatim}
void F() {
  int x; x = 1;
  int y;
  int z; z = x * 2;
}
\end{verbatim}

\textit{end example]}

15.5.2 Local constant declarations

A \textit{local-constant-declaration} declares one or more local constants.

\begin{verbatim}
local-constant-declaration:
  \textit{const}  type  constant-declarators

constant-declarators:
  constant-declarator
  constant-declarators ,  constant-declarator

constant-declarator:
  identifier  =  constant-expression
\end{verbatim}
The type of a local-constant-declaration specifies the type of the constants introduced by the declaration. The type is followed by a list of constant-declarators, each of which introduces a new constant. A constant-declarator consists of an identifier that names the constant, followed by an “=” token, followed by a constant-expression (§14.16) that gives the value of the constant.

The type and constant-expression of a local constant declaration shall follow the same rules as those of a constant member declaration (§17.3).

The value of a local constant is obtained in an expression using a simple-name (§14.5.2).

The scope of a local constant is the block in which the declaration occurs. It is an error to refer to a local constant in a textual position that precedes its constant-declarator. Within the scope of a local constant, it is a compile-time error to declare another local variable or constant with the same name.

A local constant declaration that declares multiple constants is equivalent to multiple declarations of single constants with the same type.

15.6 Expression statements

An expression-statement evaluates a given expression. The value computed by the expression, if any, is discarded.

```
expression-statement:
  statement-expression ;

statement-expression:
  invocation-expression
  object-creation-expression
  assignment
  post-increment-expression
  post-decrement-expression
  pre-increment-expression
  pre-decrement-expression
```

Not all expressions are permitted as statements. [Note: In particular, expressions such as `x + y` and `x == 1`, that merely compute a value (which will be discarded), are not permitted as statements. end note]

Execution of an expression statement evaluates the contained expression and then transfers control to the end point of the expression statement. The end point of an expression-statement is reachable if that expression-statement is reachable.

15.7 Selection statements

Selection statements select one of a number of possible statements for execution based on the value of some expression.

```
selection-statement:
  if-statement
  switch-statement
```

15.7.1 The if statement

The if statement selects a statement for execution based on the value of a Boolean expression.

```
if-statement:
  if ( boolean-expression ) embedded-statement
  if ( boolean-expression ) embedded-statement else embedded-statement
```

An else part is associated with the lexically nearest preceding if that is allowed by the syntax. [Example: Thus, an if statement of the form

```
  if (x) if (y) F(); else G();
```
is equivalent to

```c
if (x) {
    if (y) {
        F();
    }
    else {
        G();
    }
}
```

An `if` statement is executed as follows:

- The `boolean-expression` (§14.17) is evaluated.
- If the Boolean expression yields `true`, control is transferred to the first embedded statement. When and if control reaches the end point of that statement, control is transferred to the end point of the `if` statement.
- If the Boolean expression yields `false` and if an `else` part is present, control is transferred to the second embedded statement. When and if control reaches the end point of that statement, control is transferred to the end point of the `if` statement.
- If the Boolean expression yields `false` and if an `else` part is not present, control is transferred to the end point of the `if` statement.

The first embedded statement of an `if` statement is reachable if the `if` statement is reachable and the Boolean expression does not have the constant value `false`.

The second embedded statement of an `if` statement, if present, is reachable if the `if` statement is reachable and the Boolean expression does not have the constant value `true`.

The end point of an `if` statement is reachable if the end point of at least one of its embedded statements is reachable. In addition, the end point of an `if` statement with no `else` part is reachable if the `if` statement is reachable and the Boolean expression does not have the constant value `true`.

### 15.7.2 The switch statement

The switch statement selects for execution a statement list having an associated switch label that corresponds to the value of the switch expression.

```
switch-statement:
    switch ( expression ) switch-block

switch-block:
    {   switch-sections_opt   }

switch-sections:
    switch-section
    switch-sections    switch-section

switch-section:
    switch-labels    statement-list

switch-labels:
    switch-label
    switch-labels    switch-label

switch-label:
    case   constant-expression   :
    default   :
```

A `switch-statement` consists of the keyword `switch`, followed by a parenthesized expression (called the switch expression), followed by a `switch-block`. The `switch-block` consists of zero or more `switch-sections`,
enclosed in braces. Each switch-section consists of one or more switch-labels followed by a statement-list (§15.2.1).

The governing type of a switch statement is established by the switch expression. If the type of the switch expression is sbyte, byte, short, ushort, int, uint, long, ulong, char, string, or an enum-type, then that is the governing type of the switch statement. Otherwise, exactly one user-defined implicit conversion operator (§13.4) shall exist from the type of the switch expression or a base type of this type to one of the following possible governing types: sbyte, byte, short, ushort, int, uint, long, ulong, char, string. If no such implicit conversion operator exists, or if more than one such implicit conversion operator exists, a compile-time error occurs.

The constant expression of each case label shall denote a value of a type that is implicitly convertible (§13.1) to the governing type of the switch statement. A compile-time error occurs if two or more case labels in the same switch statement specify the same constant value.

There can be at most one default label in a switch statement.

A switch statement is executed as follows:

- The switch expression is evaluated and converted to the governing type.
- If one of the constants specified in a case label in the same switch statement is equal to the value of the switch expression, control is transferred to the statement list following the matched case label.
- If none of the constants specified in case labels in the same switch statement is equal to the value of the switch expression, and if a default label is present, control is transferred to the statement list following the default label.
- If none of the constants specified in case labels in the same switch statement is equal to the value of the switch expression, and if no default label is present, control is transferred to the end point of the switch statement.

If the end point of the statement list of a switch section is reachable, a compile-time error occurs. This is known as the “no fall through” rule. [Example: The example]

```csharp
switch (i) {
    case 0:
        CaseZero();
        break;
    case 1:
        CaseOne();
        break;
    default:
        CaseOthers();
        break;
}
```

is valid because no switch section has a reachable end point. Unlike C and C++, execution of a switch section is not permitted to “fall through” to the next switch section, and the example

```csharp
switch (i) {
    case 0:
        CaseZero();
    case 1:
        CaseZeroOrOne();
    default:
        CaseAny();
}
```

results in a compile-time error. When execution of a switch section is to be followed by execution of another switch section, an explicit goto case or goto default statement shall be used: 
switch (i) {
    case 0:
        CaseZero();
        goto case 1;
    case 1:
        CaseZeroOrOne();
        goto default;
    default:
        CaseAny();
        break;
}

end example

Multiple labels are permitted in a switch-section. [Example: The example

switch (i) {
    case 0:
        CaseZero();
        break;
    case 1:
        CaseOne();
        break;
    case 2:
    default:
        CaseTwo();
        break;
}

is valid. The example does not violate the “no fall through” rule because the labels case 2: and default: are part of the same switch-section. end example]

[Note: The “no fall through” rule prevents a common class of bugs that occur in C and C++ when break statements are accidentally omitted. In addition, because of this rule, the switch sections of a switch statement can be arbitrarily rearranged without affecting the behavior of the statement. For example, the sections of the switch statement above can be reversed without affecting the behavior of the statement:

switch (i) {
    default:
        CaseAny();
        break;
    case 1:
        CaseZeroOrOne();
        goto default;
    case 0:
        CaseZero();
        goto case 1;
}

end note]

[Note: The statement list of a switch section typically ends in a break, goto case, or goto default statement, but any construct that renders the end point of the statement list unreachable is permitted. For example, a while statement controlled by the Boolean expression true is known to never reach its end point. Likewise, a throw or return statement always transfers control elsewhere and never reaches its end point. Thus, the following example is valid:

switch (i) {
    case 0:
        while (true) F();
    case 1:
        throw new ArgumentException();
    case 2:
        return;
}

end note]

[Example: The governing type of a switch statement can be the type string. For example:
void DoCommand(string command) {
    switch (command.ToLower()) {
    case "run":
        DoRun();
        break;
    case "save":
        DoSave();
        break;
    case "quit":
        DoQuit();
        break;
    default:
        InvalidCommand(command);
        break;
    }
}

[Note: Like the string equality operators (§14.9.7), the switch statement is case sensitive and will execute a given switch section only if the switch expression string exactly matches a case label constant. end note]

When the governing type of a switch statement is string, the value null is permitted as a case label constant.

The statement-lists of a switch-block can contain declaration statements (§15.5). The scope of a local variable or constant declared in a switch block is the switch block.

Within a switch block, the meaning of a name used in an expression context shall always be the same (§14.5.2.1).

The statement list of a given switch section is reachable if the switch statement is reachable and at least one of the following is true:

- The switch expression is a non-constant value.
- The switch expression is a constant value that matches a case label in the switch section.
- The switch expression is a constant value that doesn’t match any case label, and the switch section contains the default label.
- A switch label of the switch section is referenced by a reachable goto case or goto default statement.

The end point of a switch statement is reachable if at least one of the following is true:

- The switch statement contains a reachable break statement that exits the switch statement.
- The switch statement is reachable, the switch expression is a non-constant value, and no default label is present.
- The switch statement is reachable, the switch expression is a constant value that doesn’t match any case label, and no default label is present.

15.8 Iteration statements

Iteration statements repeatedly execute an embedded statement.

iteration-statement:
  while-statement
  do-statement
  for-statement
  foreach-statement

15.8.1 The while statement

The while statement conditionally executes an embedded statement zero or more times.
while-statement:
while ( boolean-expression ) embedded-statement

A while statement is executed as follows:

- The boolean-expression (§14.17) is evaluated.
- If the Boolean expression yields true, control is transferred to the embedded statement. When and if control reaches the end point of the embedded statement (possibly from execution of a continue statement), control is transferred to the beginning of the while statement.
- If the Boolean expression yields false, control is transferred to the end point of the while statement.

Within the embedded statement of a while statement, a break statement (§15.9.1) can be used to transfer control to the end point of the while statement (thus ending iteration of the embedded statement), and a continue statement (§15.9.2) can be used to transfer control to the end point of the embedded statement (thus performing another iteration of the while statement).

The embedded statement of a while statement is reachable if the while statement is reachable and the Boolean expression does not have the constant value false.

The end point of a while statement is reachable if at least one of the following is true:

- The while statement contains a reachable break statement that exits the while statement.
- The while statement is reachable and the Boolean expression does not have the constant value true.

15.8.2 The do statement

The do statement conditionally executes an embedded statement one or more times.

do-statement:
do embedded-statement while ( boolean-expression );

A do statement is executed as follows:

- Control is transferred to the embedded statement.
- When and if control reaches the end point of the embedded statement (possibly from execution of a continue statement), the boolean-expression (§14.17) is evaluated. If the Boolean expression yields true, control is transferred to the beginning of the do statement. Otherwise, control is transferred to the end point of the do statement.

Within the embedded statement of a do statement, a break statement (§15.9.1) can be used to transfer control to the end point of the do statement (thus ending iteration of the embedded statement), and a continue statement (§15.9.2) can be used to transfer control to the end point of the embedded statement (thus performing another iteration of the do statement).

The embedded statement of a do statement is reachable if the do statement is reachable.

The end point of a do statement is reachable if at least one of the following is true:

- The do statement contains a reachable break statement that exits the do statement.
- The end point of the embedded statement is reachable and the Boolean expression does not have the constant value true.

15.8.3 The for statement

The for statement evaluates a sequence of initialization expressions and then, while a condition is true, repeatedly executes an embedded statement and evaluates a sequence of iteration expressions.

for-statement:
for ( for-initializer_{opt} ; for-condition_{opt} ; for-iterator_{opt} ) embedded-statement
The \texttt{for-initializer}, if present, consists of either a \texttt{local-variable-declaration} (§15.5.1) or a list of \texttt{statement-expressions} (§15.6) separated by commas. The scope of a local variable declared by a \texttt{for-initializer} starts at the \texttt{local-variable-declarator} for the variable and extends to the end of the embedded statement. The scope includes the \texttt{for-condition} and the \texttt{for-iterator}.

The \texttt{for-condition}, if present, shall be a \texttt{boolean-expression} (§14.17).

The \texttt{for-iterator}, if present, consists of a list of \texttt{statement-expressions} (§15.6) separated by commas.

A \texttt{for} statement is executed as follows:

- If a \texttt{for-initializer} is present, the variable initializers or statement expressions are executed in the order they are written. This step is only performed once.
- If a \texttt{for-condition} is present, it is evaluated.
- If the \texttt{for-condition} is not present or if the evaluation yields \texttt{true}, control is transferred to the embedded statement. When and if control reaches the end point of the embedded statement (possibly from execution of a \texttt{continue} statement), the expressions of the \texttt{for-iterator}, if any, are evaluated in sequence, and then another iteration is performed, starting with evaluation of the \texttt{for-condition} in the step above.
- If the \texttt{for-condition} is present and the evaluation yields \texttt{false}, control is transferred to the end point of the \texttt{for} statement.

Within the embedded statement of a \texttt{for} statement, a \texttt{break} statement (§15.9.1) can be used to transfer control to the end point of the \texttt{for} statement (thus ending iteration of the embedded statement), and a \texttt{continue} statement (§15.9.2) can be used to transfer control to the end point of the embedded statement (thus executing another iteration of the \texttt{for} statement).

The embedded statement of a \texttt{for} statement is reachable if one of the following is true:

- The \texttt{for} statement is reachable and no \texttt{for-condition} is present.
- The \texttt{for} statement is reachable and a \texttt{for-condition} is present and does not have the constant value \texttt{false}.

The end point of a \texttt{for} statement is reachable if at least one of the following is true:

- The \texttt{for} statement contains a reachable \texttt{break} statement that exits the \texttt{for} statement.
- The \texttt{for} statement is reachable and a \texttt{for-condition} is present and does not have the constant value \texttt{true}.

\subsection*{15.8.4 The \texttt{foreach} statement}

The \texttt{foreach} statement enumerates the elements of a collection, executing an embedded statement for each element of the collection.

\begin{verbatim}
foreach-statement:
    foreach ( type identifier in expression ) embedded-statement
\end{verbatim}
The type and identifier of a foreach statement declare the iteration variable of the statement. The iteration variable corresponds to a read-only local variable with a scope that extends over the embedded statement. During execution of a foreach statement, the iteration variable represents the collection element for which an iteration is currently being performed. A compile-time error occurs if the embedded statement attempts to modify the iteration variable (via assignment or the ++ and -- operators) or pass the iteration variable as a ref or out parameter.

The compile-time processing of a foreach statement first determines the collection type, enumerator type and element type of the expression. This determination proceeds as follows:

- If the type X of expression is an array type then there is an implicit reference conversion from X to the System.Collections.IEnumerable interface (since System.Array implements this interface). The collection type is the System.Collections.IEnumerable interface, the enumerator type is the System.Collections.IEnumerator interface and the element type is the element type of the array type X.

- Otherwise, determine whether the type X has an appropriate GetEnumerator method:
  - Perform member lookup on the type X with identifier GetEnumerator and no type arguments. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match that is not a method group, check for an enumerable interface as described below. It is recommended that a warning be issued if member lookup produces anything except a method group or no match.
  - Perform overload resolution using the resulting method group and an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, check for an enumerable interface as described below. It is recommended that a warning be issued if overload resolution produces anything except an unambiguous public instance method or no applicable methods.
  - If the return type E of the GetEnumerator method is not a class, struct or interface type, an error is produced and no further steps are taken.
  - Member lookup is performed on E with the identifier Current and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a public instance property that permits reading, an error is produced and no further steps are taken.
  - Member lookup is performed on E with the identifier MoveNext and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a method group, an error is produced and no further steps are taken.
  - Overload resolution is performed on the method group with an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, or its return type is not bool, an error is produced and no further steps are taken.
  - The collection type is X, the enumerator type is E, and the element type is the type of the Current property.

- Otherwise, check for an enumerable interface:
  - If there is exactly one type T such that there is an implicit conversion from X to the interface System.Collections.Generic.IEnumerable<T>, then the collection type is this interface, the enumerator type is the interface System.Collections.Generic.IEnumerator<T>, and the element type is T.
  - Otherwise, if there is more than one such type T, then an error is produced and no further steps are taken.
  - Otherwise, if there is an implicit conversion from X to the System.Collections.IEnumerable interface, then the collection type is this interface, the enumerator type is the interface System.Collections.IEnumerator, and the element type is object.
o Otherwise, an error is produced and no further steps are taken.

The above steps, if successful, unambiguously produce a collection type \( C \), enumerator type \( E \) and element type \( T \). A foreach statement of the form

\[
\text{foreach (V v in x) embedded-statement}
\]

is then expanded to:

\[
\{ \\
\quad E \ e = ((C)(x)).GetEnumerator(); \\
\quad \text{try} \{ \\
\quad \quad V \ v; \\
\quad \quad \text{while (e.MoveNext())} \{ \\

\]

The variable \( e \) is not visible to or accessible to the expression \( x \) or the embedded statement or any other source code of the program. The variable \( v \) is read-only in the embedded statement. If there is not an explicit conversion (§13.2) from \( T \) (the element type) to \( V \) (the type in the foreach statement), an error is produced and no further steps are taken. [Note: If \( x \) has the value null, a System.NullReferenceException is thrown at run-time. end note]

The body of the finally block is constructed according to the following steps:

- If there is an implicit conversion from \( E \) to the System.IDisposable interface, then the finally clause is expanded to the semantic equivalent of:

\[
\text{finally} \{ \\
\quad ((\text{System.IDisposable})e).Dispose(); \\
\} \\
\]

except that if \( e \) is a value type, or a type parameter instantiated to a value type, then the cast of \( e \) to System.IDisposable shall not cause boxing to occur.

- Otherwise, if \( E \) is a sealed type, the finally clause is expanded to an empty block:

\[
\text{finally} \{ \\
\} \\
\]

- Otherwise, the finally clause is expanded to:

\[
\text{finally} \{ \\
\quad \text{System.IDisposable d = e as System.IDisposable; } \\
\quad \text{if (d !null) d.Dispose(); } \\
\} \\
\]

The local \( d \) is not visible to or accessible to any user code. In particular, it does not conflict with any other variable whose scope includes the finally block.

The order in which foreach traverses the elements of an array, is as follows: For single-dimensional arrays elements are traversed in increasing index order, starting with index 0 and ending with index Length – 1. For multi-dimensional arrays, elements are traversed such that the indices of the rightmost dimension are increased first, then the next left dimension, and so on to the left.

[Example: The following example prints out each value in a two-dimensional array, in element order:

\[
\text{using System;}
\]

\[
\]
class Test
{
    static void Main()
    {
        int[,] values = {
            {1, 2, 3, 4},
            {5, 6, 7, 8}
        };

        foreach (int elementValue in values)
        {
            Console.Write("{0} ", elementValue);
            Console.WriteLine();
        }
    }
}

The output produced is as follows:
1 2 3 4 5 6 7 8

15.9 Jump statements
Jump statements unconditionally transfer control.

jump-statement:
    break-statement
    continue-statement
    goto-statement
    return-statement
    throw-statement

The location to which a jump statement transfers control is called the **target** of the jump statement.

When a jump statement occurs within a block, and the target of that jump statement is outside that block, the jump statement is said to **exit** the block. While a jump statement can transfer control out of a block, it can never transfer control into a block.

Execution of jump statements is complicated by the presence of intervening **try** statements. In the absence of such **try** statements, a jump statement unconditionally transfers control from the jump statement to its target. In the presence of such intervening **try** statements, execution is more complex. If the jump statement exits one or more **try** blocks with associated **finally** blocks, control is initially transferred to the **finally** block of the innermost **try** statement. When and if control reaches the end point of a **finally** block, control is transferred to the **finally** block of the next enclosing **try** statement. This process is repeated until the **finally** blocks of all intervening **try** statements have been executed.

*Example:* In the following code

```csharp
using System;
```
class Test
{
    static void Main() {
        while (true) {
            try {
                try {
                    Console.WriteLine("Before break");
                    break;
                }
                finally {
                    Console.WriteLine("Innermost finally block");
                }
            }
            finally {
                Console.WriteLine("Outermost finally block");
            }
        }
        Console.WriteLine("After break");
    }
}

the finally blocks associated with two try statements are executed before control is transferred to the target of the jump statement.

The output produced is as follows:

Before break
Innermost finally block
Outermost finally block
After break

end example]

15.9.1 The break statement

The break statement exits the nearest enclosing switch, while, do, for, or foreach statement.

    break-statement:
    break ;

The target of a break statement is the end point of the nearest enclosing switch, while, do, for, or foreach statement. If a break statement is not enclosed by a switch, while, do, for, or foreach statement, a compile-time error occurs.

When multiple switch, while, do, for, or foreach statements are nested within each other, a break statement applies only to the innermost statement. To transfer control across multiple nesting levels, a goto statement (§15.9.3) shall be used.

A break statement cannot exit a finally block (§15.10). When a break statement occurs within a finally block, the target of the break statement shall be within the same finally block; otherwise a compile-time error occurs.

A break statement is executed as follows:

- If the break statement exits one or more try blocks with associated finally blocks, control is initially transferred to the finally block of the innermost try statement. When and if control reaches the end point of a finally block, control is transferred to the finally block of the next enclosing try statement. This process is repeated until the finally blocks of all intervening try statements have been executed.

- Control is transferred to the target of the break statement.

Because a break statement unconditionally transfers control elsewhere, the end point of a break statement is never reachable.
15.9.2 The continue statement

The continue statement starts a new iteration of the nearest enclosing while, do, for, or foreach statement.

```
continue-statement:
    continue ;
```

The target of a continue statement is the end point of the embedded statement of the nearest enclosing while, do, for, or foreach statement. If a continue statement is not enclosed by a while, do, for, or foreach statement, a compile-time error occurs.

When multiple while, do, for, or foreach statements are nested within each other, a continue statement applies only to the innermost statement. To transfer control across multiple nesting levels, a goto statement (§15.9.3) shall be used.

A continue statement cannot exit a finally block (§15.10). When a continue statement occurs within a finally block, the target of the continue statement shall be within the same finally block; otherwise a compile-time error occurs.

A continue statement is executed as follows:

- If the continue statement exits one or more try blocks with associated finally blocks, control is initially transferred to the finally block of the innermost try statement. When and if control reaches the end point of a finally block, control is transferred to the finally block of the next enclosing try statement. This process is repeated until the finally blocks of all intervening try statements have been executed.

- Control is transferred to the target of the continue statement.

Because a continue statement unconditionally transfers control elsewhere, the end point of a continue statement is never reachable.

15.9.3 The goto statement

The goto statement transfers control to a statement that is marked by a label.

```
goto-statement:
    goto identifier ;
    goto case constant-expression ;
    goto default ;
```

The target of a goto identifier statement is the labeled statement with the given label. If a label with the given name does not exist in the current function member, or if the goto statement is not within the scope of the label, a compile-time error occurs. [Note: This rule permits the use of a goto statement to transfer control out of a nested scope, but not into a nested scope. In the example]

```csharp
using System;

class Test {
    static void Main(string[] args) {
        string[,] table = {
            {"red", "blue", "green"},
            {"Monday", "Wednesday", "Friday"}
        };
        foreach (string str in args) {
            int row, colm;
            for (row = 0; row <= 1; ++row)
                for (colm = 0; colm <= 2; ++colm)
                    if (str == table[row, colm])
                        goto done;
```
C# LANGUAGE SPECIFICATION

```csharp
C# LANGUAGE SPECIFICATION

```a goto statement is used to transfer control out of a nested scope. end note]a goto statement is used to transfer control out of a nested scope. end note]
The target of a goto case statement is the statement list in the immediately enclosing switch statement
§15.7.2 which contains a case label with the given constant value. If the goto case statement is not
enclosed by a switch statement, if the constant-expression is not implicitly convertible (§13.1) to the
governing type of the nearest enclosing switch statement, or if the nearest enclosing switch statement
does not contain a case label with the given constant value, a compile-time error occurs.
The target of a goto default statement is the statement list in the immediately enclosing switch statement
§15.7.2, which contains a default label. If the goto default statement is not enclosed by a switch
statement, or if the nearest enclosing switch statement does not contain a default label, a compile-time
error occurs.
A goto statement cannot exit a finally block §15.10. When a goto statement occurs within a finally
block, the target of the goto statement shall be within the same finally block, or otherwise a compile-
time error occurs.
A goto statement is executed as follows:
• If the goto statement exits one or more try blocks with associated finally blocks, control is initially
transferred to the finally block of the innermost try statement. When and if control reaches the end
point of a finally block, control is transferred to the finally block of the next enclosing try
statement. This process is repeated until the finally blocks of all intervening try statements have
been executed.
• Control is transferred to the target of the goto statement.
Because a goto statement unconditionally transfers control elsewhere, the end point of a goto statement is
never reachable.
15.9.4 The return statement
The return statement returns control to the caller of the function member in which the return statement
appears.
```csharp

```csharp
A return statement with no expression can be used only in a function member that does not compute a
value; that is, a method with the return type void, the set accessor of a property or indexer, the add and
remove accessors of an event, an instance constructor, static constructor, or a finalizer.
A return statement with an expression can only be used in a function member that computes a value, that
is, a method with a non-void return type, the get accessor of a property or indexer, or a user-defined
operator. An implicit conversion (§13.1) shall exist from the type of the expression to the return type of the
containing function member.
It is a compile-time error for a return statement to appear in a finally block §15.10.
A return statement is executed as follows:
• If the return statement specifies an expression, the expression is evaluated and the resulting value is
converted to the return type of the containing function member by an implicit conversion. The result of
the conversion becomes the value returned to the caller.

238
• If the `return` statement is enclosed by one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all enclosing `try` statements have been executed.

• Control is returned to the caller of the containing function member.

Because a `return` statement unconditionally transfers control elsewhere, the end point of a `return` statement is never reachable.

### 15.9.5 The `throw` statement

The `throw` statement throws an exception.

```
throw-statement:  
  throw expressionopt ;
```

A `throw` statement with an expression throws the value produced by evaluating the expression. The expression shall denote a value of the class type `System.Exception` or of a class type that derives from `System.Exception`. If evaluation of the expression produces `null`, a `System.NullReferenceException` is thrown instead.

The `throw` statement can be used with an expression whose type is given by a type parameter (§25.1.1) only if that type parameter has `System.Exception` (or a subclass thereof) as its effective base class (§25.7).

A `throw` statement with no expression can be used only in a `catch` block, in which case, that statement re-throws the exception that is currently being handled by that `catch` block.

Because a `throw` statement unconditionally transfers control elsewhere, the end point of a `throw` statement is never reachable.

When an exception is thrown, control is transferred to the first `catch` clause in an enclosing `try` statement that can handle the exception. The process that takes place from the point of the exception being thrown to the point of transferring control to a suitable exception handler is known as exception propagation.

Propagation of an exception consists of repeatedly evaluating the following steps until a `catch` clause that matches the exception is found. In this description, the `throw point` is initially the location at which the exception is thrown.

• In the current function member, each `try` statement that encloses the throw point is examined. For each statement S, starting with the innermost `try` statement and ending with the outermost `try` statement, the following steps are evaluated:
  o If the `try` block of S encloses the throw point and if S has one or more `catch` clauses, the `catch` clauses are examined in order of appearance to locate a suitable handler for the exception. The first `catch` clause that specifies the exception type or a base type of the exception type is considered a match. A general `catch` (§15.10) clause is considered a match for any exception type. If a matching `catch` clause is located, the exception propagation is completed by transferring control to the block of that `catch` clause.
  o Otherwise, if the `try` block or a `catch` block of S encloses the throw point and if S has a `finally` block, control is transferred to the `finally` block. If the `finally` block throws another exception, processing of the current exception is terminated. Otherwise, when control reaches the end point of the `finally` block, processing of the current exception is continued.

• If an exception handler was not located in the current function member invocation, the function member invocation is terminated. The steps above are then repeated for the caller of the function member with a throw point corresponding to the statement from which the function member was invoked.

• If the exception processing terminates all function member invocations in the current thread, indicating that the thread has no handler for the exception, then the thread is itself terminated. The impact of such termination is implementation-defined.
15.10 The try statement

The `try` statement provides a mechanism for catching exceptions that occur during execution of a block. Furthermore, the `try` statement provides the ability to specify a block of code that is always executed when control leaves the `try` statement.

```
try-statement:
  try  block  catch-clauses
  try  block  catch-clauses_opt  finally-clause

catch-clauses:
  specific-catch-clauses
  specific-catch-clauses_opt  general-catch-clause

specific-catch-clauses:
  specific-catch-clause
  specific-catch-clauses  specific-catch-clause

specific-catch-clause:
  catch  (  class-type  identifier_opt  )  block

general-catch-clause:
  catch  block

finally-clause:
  finally  block
```

There are three possible forms of `try` statements:

- A `try` block followed by one or more `catch` blocks.
- A `try` block followed by a `finally` block.
- A `try` block followed by one or more `catch` blocks followed by a `finally` block.

When a `catch` clause specifies a `class-type`, the type shall be `System.Exception` or a type that derives from `System.Exception`.

When a `catch` clause specifies both a `class-type` and an `identifier`, an `exception variable` of the given name and type is declared. The exception variable corresponds to a local variable with a scope that extends over the `catch` block. During execution of the `catch` block, the exception variable represents the exception currently being handled. For purposes of definite assignment checking, the exception variable is considered definitely assigned in its entire scope.

Unless a `catch` clause includes an exception variable name, it is impossible to access the exception object in the `catch` block.

The type named in a `catch` clause can be a type parameter only if that type parameter (§25.1.1) has `System.Exception` (or a subclass thereof) as its effective base class (§25.7).

A `catch` clause that specifies neither an exception type nor an exception variable name is called a general `catch` clause. A `try` statement can only have one general `catch` clause, and, if one is present, it shall be the last `catch` clause.

[Note: Some environments, especially those supporting multiple languages, might support exceptions that are not representable as an object derived from `System.Exception`, although such an exception could never be generated by C# code. In such an environment, a general catch clause might be used to catch such an exception. Thus, a general catch clause is semantically different from one that specifies the type `System.Exception`, in that the former might also catch exceptions from other languages. end note]

In order to locate a handler for an exception, `catch` clauses are examined in lexical order. A compile-time error occurs if a `catch` clause specifies a type that is the same as, or is derived from, a type that was specified in an earlier `catch` clause for the same `try`. [Note: Without this restriction, it would be possible to write unreachable `catch` clauses. end note]
Within a `catch` block, a `throw` statement (§15.9.5) with no expression can be used to re-throw the exception that was caught by the `catch` block. Assignments to an exception variable do not alter the exception that is re-thrown.

[Example: In the following code]
```
using System;

class Test {
    static void F() {
        try {
            G();
        } catch (Exception e) {
            Console.WriteLine("Exception in F: " + e.Message);
            e = new Exception("F");
            throw;  // re-throw
        }
    }
    static void G() {
        throw new Exception("G");
    }
    static void Main() {
        try {
            F();
        } catch (Exception e) {
            Console.WriteLine("Exception in Main: " + e.Message);
        }
    }
}
```
the method `F` catches an exception, writes some diagnostic information to the console, alters the exception variable, and re-throws the exception. The exception that is re-thrown is the original exception, so the output produced is:

```
Exception in F: G
Exception in Main: G
```
If the first catch block had thrown `e` instead of rethrowing the current exception, the output produced would be as follows:

```
Exception in F: G
Exception in Main: F
```

[end example]

It is a compile-time error for a `break`, `continue`, or `goto` statement to transfer control out of a `finally` block. When a `break`, `continue`, or `goto` statement occurs in a `finally` block, the target of the statement shall be within the same `finally` block, or otherwise a compile-time error occurs.

It is a compile-time error for a `return` statement to occur in a `finally` block.

A `try` statement is executed as follows:

- Control is transferred to the `try` block.
- When and if control reaches the end point of the `try` block:
  - If the `try` statement has a `finally` block, the `finally` block is executed.
  - Control is transferred to the end point of the `try` statement.
- If an exception is propagated to the `try` statement during execution of the `try` block:
  - The `catch` clauses, if any, are examined in order of appearance to locate a suitable handler for the exception. The first `catch` clause that specifies the exception type or a base type of the exception...
type is considered a match. A general catch clause is considered a match for any exception type. If a matching catch clause is located:

- If the matching catch clause declares an exception variable, the exception object is assigned to the exception variable.
- Control is transferred to the matching catch block.
- When and if control reaches the end point of the catch block:
  - If the try statement has a finally block, the finally block is executed.
  - Control is transferred to the end point of the try statement.
- If an exception is propagated to the try statement during execution of the catch block:
  - If the try statement has a finally block, the finally block is executed.
  - The exception is propagated to the next enclosing try statement.
  - If the try statement has no catch clauses or if no catch clause matches the exception:
    - If the try statement has a finally block, the finally block is executed.
    - The exception is propagated to the next enclosing try statement.

The statements of a finally block are always executed when control leaves a try statement. This is true whether the control transfer occurs as a result of normal execution, as a result of executing a break, continue, goto, or return statement, or as a result of propagating an exception out of the try statement.

If an exception is thrown during execution of a finally block, the exception is propagated to the next enclosing try statement. If another exception was in the process of being propagated, that exception is lost. The process of propagating an exception is discussed further in the description of the throw statement (§15.9.5).

The try block of a try statement is reachable if the try statement is reachable.

A catch block of a try statement is reachable if the try statement is reachable.

The finally block of a try statement is reachable if the try statement is reachable.

The end point of a try statement is reachable if both of the following are true:

- The end point of the try block is reachable or the end point of at least one catch block is reachable.
- If a finally block is present, the end point of the finally block is reachable.

15.11 The checked and unchecked statements

The checked and unchecked statements are used to control the overflow-checking context for integral-type arithmetic operations and conversions.

```plaintext
checked-statement:
  checked  block

unchecked-statement:
  unchecked  block
```

The checked statement causes all expressions in the block to be evaluated in a checked context, and the unchecked statement causes all expressions in the block to be evaluated in an unchecked context.

The checked and unchecked statements are precisely equivalent to the checked and unchecked operators (§14.5.12), except that they operate on blocks instead of expressions.
15.12 The lock statement

The `lock` statement obtains the mutual-exclusion lock for a given object, executes a statement, and then releases the lock.

\[
\text{lock-statement:} \\
\quad \text{lock ( expression ) embedded-statement}
\]

The compile time type of the expression of a `lock` statement shall be a `reference-type` or a type parameter (§25.1.1) known to be a reference type. It is a compile-time error for the compile time type of the expression to denote a `value-type`.

A `lock` statement of the form

\[
\text{lock (x) ...}
\]

is precisely equivalent to:

\[
\text{object obj = x; System.Threading.Monitor.Enter(obj); try { ... finally { System.Threading.Monitor.Exit(obj); }}
\]

[Example:

```csharp
class Cache
{
    public void Add(object x) {
        lock (key) {
            ...
        }
    }
    public void Remove(object x) {
        lock (key) {
            ...
        }
    }
    private readonly object key = new object();
}
```

end example]

15.13 The using statement

The `using` statement obtains one or more resources, executes a statement, and then disposes of the resource.

\[
\text{using-statement:} \\
\quad \text{using ( resource-acquisition ) embedded-statement}
\]

A `resource` is a class or struct that implements the `System.IDisposable` interface. The `System.IDisposable` interface includes a single parameterless method named `Dispose`. Code that is using a resource can call `Dispose` to indicate that the resource is no longer needed. If `Dispose` is not called, then automatic disposal eventually occurs as a consequence of garbage collection (assuming the finalizer of the resource type calls `Dispose` or otherwise performs the equivalent actions).

Local variables declared in a `resource-acquisition` are read-only, and shall include an initializer. A compile-time error occurs if the embedded statement attempts to modify these local variables (via assignment or the `++` and `--` operators) or pass them as `ref` or `out` parameters.
A using statement is translated into three parts: acquisition, usage, and disposal. Usage of the resource is implicitly enclosed in a try statement that includes a finally clause. This finally clause disposes of the resource. If a null resource is acquired, then no call to Dispose is made, and no exception is thrown.

A using statement of the form

```
using (expression) embedded-statement
```

is equivalent to a using statement of the form:

```
using (ResourceType resource = expression) embedded-statement
```

where ResourceType is the type of the expression and the resource variable is not visible to or accessible from any source code of the program.

A using statement of the form

```
using (ResourceType resource = expression) embedded-statement
```

corresponds to the expansion:

```csharp
{
    ResourceType resource = expression;
    try {
        embedded-statement
    }
    finally {
        ... // Dispose of resource
    }
}
```

The resource variable is read-only in the embedded statement.

The precise form of the finally block is determined as follows:

- If there is not an implicit conversion from ResourceType to the System.IDisposable interface, then a compile-time error is produced.
- Otherwise, if ResourceType is a value type or a type parameter with the value type constraint (§25.7), the finally clause is expanded to the semantic equivalent of:
  ```csharp
  finally {
      ((System.IDisposable)resource).Dispose();
  }
  ```
  except that casting resource to System.IDisposable shall not cause boxing to occur.
- Otherwise, the finally clause is expanded to:
  ```csharp
  finally {
      if (resource != null) ((System.IDisposable)resource).Dispose();
  }
  ```

When a resource-acquisition takes the form of a local-variable-declaration, it is possible to acquire multiple resources of a given type. A using statement of the form

```
using (ResourceType r1 = e1, r2 = e2, ..., rN = eN) statement
```

is precisely equivalent to a sequence of nested using statements:

```
using (ResourceType r1 = e1)
    using (ResourceType r2 = e2)
        ...
    using (ResourceType rN = eN)
statement
```

[Example: The example below creates a file named log.txt and writes two lines of text to the file. The example then opens that same file for reading and copies the contained lines of text to the console.]

```
using System;
using System.IO;
```
class Test
{
    static void Main() {
        using (TextWriter w = File.CreateText("log.txt")) {
            w.WriteLine("This is line one");
            w.WriteLine("This is line two");
        }
        using (TextReader r = File.OpenText("log.txt")) {
            string s;
            while ((s = r.ReadLine()) != null) {
                Console.WriteLine(s);
            }
        }
    }
}

Since the TextWriter and TextReader classes implement the IDisposable interface, the example can use using statements to ensure that the underlying file is properly closed following the write or read operations. end example]

15.14 The yield statement

The yield statement is used in an iterator block (§26.1) to yield a value to the enumerator object or to signal the end of the iteration.

yield-statement:
    yield return expression ;
    yield break ;

To ensure compatibility with existing programs, yield is not a keyword; yield has special meaning only when it is used immediately before a return or break keyword. In other contexts, yield can be used as an identifier.

The are several restrictions on where a yield statement can appear, as described in the following.

- It is a compile-time error for a yield statement (of either form) to appear outside a method-body, operator-body, or accessor-body.
- It is a compile-time error for a yield statement (of either form) to appear inside an anonymous method.
- It is a compile-time error for a yield statement (of either form) to appear in the finally clause of a try statement.
- It is a compile-time error for a yield return statement to appear anywhere in a try statement that contains catch-clauses.

[Example: The following example shows some valid and invalid uses of yield statements.

delegate IEnumerable<int> D();
IEnumerator<int> GetEnumerator() {
    try {
        yield return 1;  // Ok
        yield break;     // Ok
    }
    finally {
        yield return 2;  // Error, yield in finally
        yield break;     // Error, yield in finally
    }
}
C# LANGUAGE SPECIFICATION

try {
    yield return 3;  // Error, yield return in try...catch
    yield break;    // Ok
} catch {
    yield return 4;  // Error, yield return in try...catch
    yield break;    // Ok
}  
D d = delegate {
    yield return 5;   // Error, yield in an anonymous method
};

int MyMethod() {
    yield return 1;   // Error, wrong return type for an iterator
}

end example]

An implicit conversion (§13.1) shall exist from the type of the expression in the `yield return` statement to the yield type (§26.1.3) of the iterator block.

A `yield return` statement is executed as follows:

- The expression given in the statement is evaluated, implicitly converted to the yield type, and assigned to the `Current` property of the enumerator object.
- Execution of the iterator block is suspended. If the `yield return` statement is within one or more `try` blocks, the associated `finally` blocks are not executed at this time.
- The `MoveNext` method of the enumerator object returns `true` to its caller, indicating that the enumerator object successfully advanced to the next item.

The next call to the enumerator object's `MoveNext` method resumes execution of the iterator block from where it was last suspended, namely at the end point of the `yield return` statement that caused the suspension.

A `yield break` statement is executed as follows:

- If the `yield break` statement is enclosed by one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all enclosing `try` statements have been executed.
- Control is returned to the caller of the iterator block. This is either the `MoveNext` method or `Dispose` method of the enumerator object.

Because a `yield break` statement unconditionally transfers control elsewhere, the end point of a `yield break` statement is never reachable.
16. Namespaces

C# programs are organized using namespaces. Namespaces are used both as an “internal” organization system for a program, and as an “external” organization system—a way of presenting program elements that are exposed to other programs.

Using directives (§16.3) are provided to facilitate the use of namespaces.

16.1 Compilation units

A compilation-unit defines the overall structure of a source file. A compilation unit consists of zero or more extern-alias-directives followed by zero or more using-directives followed by zero or more global-attributes followed by zero or more namespace-member-declarations.

\[
\text{compilation-unit: } \left( \text{extern-alias-directives}_{\text{opt}} \right) \left( \text{using-directives}_{\text{opt}} \right) \left( \text{global-attributes}_{\text{opt}} \right) \left( \text{namespace-member-declarations}_{\text{opt}} \right)
\]

A C# program consists of one or more compilation units, each contained in a separate source file. When a C# program is compiled, all of the compilation units are processed together. Thus, compilation units can depend on each other, possibly in a circular fashion.

The extern-alias-directives of a compilation unit affect the using-directives, global-attributes and namespace-member-declarations of that compilation unit, but have no effect on other compilation units.

The using-directives of a compilation unit affect the global-attributes and namespace-member-declarations of that compilation unit, but have no effect on other compilation units.

The global-attributes (§24) of a compilation unit permit the specification of attributes for the target assembly. Assemblies act as physical containers for types.

The namespace-member-declarations of each compilation unit of a program contribute members to a single declaration space called the global namespace. [Example:

File A.cs:

```csharp
class A {}
```

File B.cs:

```csharp
class B {}
```

The two compilation units contribute to the single global namespace, in this case declaring two classes with the fully qualified names A and B. Because the two compilation units contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name. end example]

16.2 Namespace declarations

A namespace-declaration consists of the keyword namespace, followed by a namespace name and body, optionally followed by a semicolon.

\[
\text{namespace-declaration: } \left( \text{namespace } \text{qualified-identifier } \text{namespace-body } ;_{\text{opt}} \right)
\]

qualified-identifier:

identifier

qualified-identifier . identifier
namespace-body:
   {  extern-alias-directives_{opt}  using-directives_{opt}  namespace-member-declarations_{opt}  }

A namespace-declaration can occur as a top-level declaration in a compilation-unit or as a member declaration within another namespace-declaration. When a namespace-declaration occurs as a top-level declaration in a compilation-unit, the namespace becomes a member of the global namespace. When a namespace-declaration occurs within another namespace-declaration, the inner namespace becomes a member of the outer namespace. In either case, the name of a namespace shall be unique within the containing namespace.

Namespaces are implicitly public and the declaration of a namespace cannot include any access modifiers.

Within a namespace-body, the optional using-directives import the names of other namespaces and types, allowing them to be referenced directly instead of through qualified names. The optional namespace-member-declarations contribute members to the declaration space of the namespace. All extern-alias-directives shall appear before any using-directives and all extern-alias-directives and using-directives shall appear before any member declarations.

The qualified-identifier of a namespace-declaration can be a single identifier or a sequence of identifiers separated by "." tokens. The latter form permits a program to define a nested namespace without lexically nesting several namespace declarations. [Example:

```
namespace N1.N2
{
    class A {}
    class B {}
}
```

is semantically equivalent to

```
namespace N1
{
    namespace N2
    {
        class A {}
        class B {}
    }
}
```

end example]

Namespaces are open-ended, and two namespace declarations with the same fully qualified name (§10.8.2) contribute to the same declaration space (§10.3). [Example: In the following code

```
namespace N1.N2
{
    class A {}
}
```

```
namespace N1.N2
{
    class B {}
}
```

the two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names N1.N2.A and N1.N2.B. Because the two declarations contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name. end example]

Namespaces whose names begin with System. are reserved for use by the Standard Library (§Annex D).

16.3 Extern alias directives

An extern-alias-directive introduces an identifier that serves as an alias for an externally defined namespace. The specification of the aliased namespace is external to the source code of the program.
extern-alias-directives:
extern-alias-directive
extern-alias-directives extern-alias-directive

extern-alias-directive:
extern alias identifier ;

The scope of an `extern-alias-directive` extends over the `using-directives`, `global-attributes` and `namespace-member-declarations` of its immediately containing `compilation-unit` or `namespace-body`. An `extern-alias-directive` contributes its name to the `alias declaration space` of the containing compilation unit or namespace body (§10.3) and not to the declaration space of the containing namespace.

Within a compilation unit or namespace body that contains an `extern-alias-directive`, the identifier introduced by the `extern-alias-directive` can be used to reference the aliased namespace. It is a compile-time error for the `identifier` to be the word `global`.

Within C# source code, a type is declared a member of a single namespace. However, a namespace hierarchy referenced by an extern alias may contain types that are also members of other namespaces. For example, if `A` and `B` are extern aliases, the names `A::X`, `B::C.Y` and `global::D.Z` may, depending on the external specification supported by the particular compiler, all refer to the same type.

The alias introduced by an `extern-alias-directive` is very similar to the alias introduced by a `using-alias-directive`. See §16.4.1 for more detailed discussion of `extern-alias-directives` and `using-alias-directives`.

Like `get` and `set` in property accessors, `alias` is not a keyword (§9.4.3). The word `alias` only has special meaning when it immediately follows the `extern` keyword in an `extern-alias-directive`. [Example: In fact an `extern` alias could use the identifier `alias` as its name:

```csharp
extern alias alias;
```]

### 16.4 Using directives

**Using directives** facilitate the use of namespaces and types defined in other namespaces. `using-directives` impact the name resolution process of `namespace-or-type-names` (§10.8) and `simple-names` (§14.5.2), but unlike declarations, `using-directives` do not contribute new members to the underlying declaration spaces of the compilation units or namespaces within which they are used.

```csharp
using-directives:
    using-directive
    using-directives using-directive
```

A `using-alias-directive` (§16.4.1) introduces an alias for a namespace or type.

A `using-namespace-directive` (§16.4.2) imports the type members of a namespace.

The scope of a `using-directive` extends over the `namespace-member-declarations` of its immediately containing compilation unit or namespace body. The scope of a `using-directive` specifically does not include its peer `using-directives`. Thus, peer `using-directives` do not affect each other, and the order in which they are written is insignificant. In contrast, the scope of an `extern-alias-directive` includes the `using-directives` defined in the same compilation unit or namespace body.

### 16.4.1 Using alias directives

A `using-alias-directive` introduces an identifier that serves as an alias for a namespace or type within the immediately enclosing compilation unit or namespace body.
using-alias-directive:
using identifier = namespace-or-type-name ;

Within global attributes and member declarations in a compilation unit or namespace body that contains a using-alias-directive, the identifier introduced by the using-alias-directive can be used to reference the given namespace or type. [Example:

```c#
namespace N1.N2
{
    class A {}
}
namespace N3
{
    using A = N1.N2.A;
    class B: A {}
}
```

Above, within member declarations in the N3 namespace, A is an alias for N1.N2.A, and thus class N3.B derives from class N1.N2.A. The same effect can be obtained by creating an alias R for N1.N2 and then referencing R.A:

```c#
namespace N3
{
    using R = N1.N2;
    class B: R.A {}
}
```

end example]

Within using directives, global attributes and member declarations in a compilation unit or namespace body that contains an extern-alias-directive, the identifier introduced by the extern-alias-directive can be used to reference the associated namespace. [Example: For example:

```c#
namespace N1
{
    extern alias N2;
    class B: N2::A {}
}
```

Above, within member declarations in the N1 namespace, N2 is an alias for some namespace whose definition is external to the source code of the program. Class N1.B derives from class N2.A. The same effect can be obtained by creating an alias A for N2.A and then referencing A:

```c#
namespace N1
{
    extern alias N2;
    using A = N2::A;
    class B: A {}
}
```

end example]

An extern-alias-directive or using-alias-directive makes an alias available within a particular compilation unit or namespace body, but it does not contribute any new members to the underlying declaration space. In other words, an alias directive is not transitive, but, rather, affects only the compilation unit or namespace body in which it occurs. [Example: In the following code

```c#
namespace N3
{
    extern alias R1;
    using R2 = N1.N2;
}
```
namespace N3
{
    class B: R1::A, R2.I {}  // Error, R1 and R2 unknown
}

the scopes of the alias directives that introduce R1 and R2 only extend to member declarations in the namespace body in which they are contained, so R1 and R2 are unknown in the second namespace declaration. However, placing the alias directives in the containing compilation unit causes the alias to become available within both namespace declarations:

```cpp
extern alias R1;
using R2 = N1.N2;
namespace N3
{
    class B: R1::A, R2.I {}  
}
namespace N3
{
    class C: R1::A, R2.I {}  
}
```

end example]

Each extern-alias-directive or using-alias-directive in a compilation-unit or namespace-body contributes a name to the alias declaration space (§10.3) of the immediately enclosing compilation-unit or namespace-body. The identifier of the alias directive shall be unique within the corresponding alias declaration space. The alias identifier need not be unique within the global declaration space or the declaration space of the corresponding namespace. [Example:

```cpp
extern alias A;
extern alias B;
using A = N1.N2;  // Error: alias A already exists
class B {}  // Ok
```

The using alias named A causes an error since there is already an alias named A in the same compilation unit. The class named B does not conflict with the extern alias named B since these names are added to distinct declaration spaces. The former is added to the global declaration space and the latter is added to the alias declaration space for this compilation unit.

When an alias name matches the name of a member of a namespace, usage of either must be appropriately qualified:

```cpp
namespace N1.N2
{
    class B {}
}
namespace N3
{
    class A {}
    class B : A {}
}
namespace N3
{
    using A = N1.N2;
    using B = N1.N2.B;
    class W : B {}  // Error: B is ambiguous
    class X : A.B {}  // Error: A is ambiguous
}
```

In the second namespace body for N3, unqualified use of B results in an error, since N3 contains a member named B and the namespace body that also declares an alias with name B; likewise for A. The class N3.B can be referenced as N3.B or global::N3.B. The alias A can be used in a qualified-alias-member (§16.7), such
as A::B. The alias B is essentially useless. It cannot be used in a qualified-alias-member since only namespace aliases can be used in a qualified-alias-member and B aliases a type. end example]

Just like regular members, names introduced by alias directives are hidden by similarly named members in nested scopes. [Example: In the following code

```csharp
using R = N1.N2;
namespace N3
{
    class R {}
    class B: R.A {}
    // Error, R has no member A
}
```
	he reference to R.A in the declaration of B causes a compile-time error because R refers to N3.R, not N1.N2. end example]

The order in which extern-alias-directives are written has no significance. Likewise, the order in which using-alias-directives are written has no significance, but all using-alias-directives must come after all extern-alias-directives in the same compilation unit or namespace body. Resolution of the namespace-or-type-name referenced by a using-alias-directive is not affected by the using-alias-directive itself or by other using-directives in the immediately containing compilation unit or namespace body, but may be affected by extern-alias-directives in the immediately containing compilation unit or namespace body. In other words, the namespace-or-type-name of a using-alias-directive is resolved as if the immediately containing compilation unit or namespace body had no using-directives but has the correct set of extern-alias-directives. [Example: In the following code

```csharp
namespace N1.N2 {}
namespace N3
{
    extern alias E;
    using R1 = E::N;   // OK
    using R2 = N1;   // OK
    using R3 = N1.N2; // OK
    using R4 = R2.N2; // Error, R2 unknown
}
```

the last using-alias-directive results in a compile-time error because it is not affected by the previous using-alias-directive. The first using-alias-directive does not result in an error since the scope of the extern alias E includes the using-alias-directive. end example]

A using-alias-directive can create an alias for any namespace or type, including the namespace within which it appears and any namespace or type nested within that namespace.

Accessing a namespace or type through an alias yields exactly the same result as accessing that namespace or type through its declared name. [Example: Given

```csharp
namespace N1.N2
{
    class A {}
}
namespace N3
{
    using R1 = N1;
    using R2 = N1.N2;
    class B
    {
        N1.N2.A a;     // refers to N1.N2.A
        R1.N2.A b;     // refers to N1.N2.A
        R2.A c;        // refers to N1.N2.A
    }
}
```
the names N1.N2.A, R1.N2.A, and R2.A are equivalent and all refer to the class whose fully qualified name is N1.N2.A. end example]

Although each part of a partial type (§17.1.4) is declared within the same namespace, the parts are typically written within different namespace declarations. Thus, different extern alias directives and using directives can be present for each part. When interpreting simple names (§14.5.2) within one part, only the extern alias directives and using directives of the namespace bodies and compilation unit enclosing that part are considered. This may result in the same identifier having different meanings in different parts. [Example:

```csharp
class A {}
```

end example]

16.4.2 Using namespace directives

A using-name-space-directive imports the types contained in a namespace into the immediately enclosing compilation unit or namespace body, enabling the identifier of each type to be used without qualification.

```
using-name-space-directive:
using namespace-name ;
```

Within member declarations in a compilation unit or namespace body that contains a using-name-space-directive, the types contained in the given namespace can be referenced directly. [Example:

```csharp
namespace N1.N2
{
 class A {}
}
namespace N3
{
 using N1.N2;
 class B: A {}
}
```

Above, within member declarations in the N3 namespace, the type members of N1.N2 are directly available, and thus class N3.B derives from class N1.N2.A. end example]

A using-name-space-directive imports the types contained in the given namespace, but specifically does not import nested namespaces. [Example: In the following code

```csharp
namespace N1.N2
{
 class A {}
}
namespace N3
{
 using N1;
```
class B: N2.A {}  // Error, N2 unknown
}

the using-name-space-directive imports the types contained in N1, but not the namespaces nested in N1. Thus, the reference to N2.A in the declaration of B results in a compile-time error because no members named N2 are in scope. end example]

Unlike a using-alias-directive, a using-name-space-directive can import types whose identifiers are already defined within the enclosing compilation unit or namespace body. In effect, names imported by a using-name-space-directive are hidden by similarly named members in the enclosing compilation unit or namespace body. [Example:

namespace N1.N2
{
  class A {}
}
namespace N3
{
  using N1.N2;
  class A {}
}

Here, within member declarations in the N3 namespace, A refers to N3.A rather than N1.N2.A. end example]

When more than one namespace imported by using-name-space-directives in the same compilation unit or namespace body contain types by the same name, references to that name are considered ambiguous. [Example: In the following code

namespace N1
{
  class A {}
}
namespace N2
{
  class A {}
}
namespace N3
{
  using N1;
  using N2;
  class B: A {}    // Error, A is ambiguous
}

both N1 and N2 contain a member A, and because N3 imports both, referencing A in N3 is a compile-time error. In this situation, the conflict can be resolved through qualification of references to A, or by introducing a using-alias-directive that picks a particular A. For example:

namespace N3
{
  using N1;
  using N2;
  using A = N1.A;
  class B: A {}    // A means N1.A
}

end example]

Like a using-alias-directive, a using-name-space-directive does not contribute any new members to the underlying declaration space of the namespace, but, rather, affects only the compilation unit or namespace body in which it appears.
The namespace-name referenced by a using-namespace-directive is resolved in the same way as the namespace-or-type-name referenced by a using-alias-directive. Thus, using-namespace-directives in the same compilation unit or namespace body do not affect each other and can be written in any order.

16.5 Namespace members

A namespace-member-declaration is either a namespace-declaration (§16.2) or a type-declaration (§16.6).

\[
\text{namespace-member-declarations:} \\
\text{namespace-member-declaration} \\
\text{namespace-member-declarations namespace-member-declaration} \\
\text{namespace-member-declaration:} \\
\text{namespace-declaration} \\
\text{type-declaration}
\]

A compilation unit or a namespace body can contain namespace-member-declarations, and such declarations contribute new members to the underlying declaration space of the containing compilation unit or namespace body.

16.6 Type declarations

A type-declaration is a class-declaration (§17.1), a struct-declaration (§18.1), an interface-declaration (§20.1), an enum-declaration (§21.1), or a delegate-declaration (§22.1).

\[
\text{type-declaration:} \\
\text{class-declaration} \\
\text{struct-declaration} \\
\text{interface-declaration} \\
\text{enum-declaration} \\
\text{delegate-declaration}
\]

A type-declaration can occur as a top-level declaration in a compilation unit or as a member declaration within a namespace, class, or struct.

When a type declaration for a type \( T \) occurs as a top-level declaration in a compilation unit, the fully qualified name (§10.8.2) of the type declaration is the same as the unqualified name of the declaration (§10.8.1). When a type declaration for a type \( T \) occurs within a namespace, class, or struct, the fully qualified name (§10.8.2) of the type declaration is \( S.N \), where \( S \) is the fully qualified name of the containing namespace or type declaration, and \( N \) is the unqualified name of the declaration (§10.8.1).

A type declared within a class or struct is called a nested type (§17.2.6).

The permitted access modifiers and the default access for a type declaration depend on the context in which the declaration takes place (§10.5.1):

- Types declared in compilation units or namespace declarations can have public or internal access. The default is internal access.
- Types declared in classes can have public, protected internal, protected, internal, or private access. The default is private access.
- Types declared in structs can have public, internal, or private access. The default is private access.

16.7 Qualified alias member

A qualified-alias-member provides explicit access to the global namespace and to extern or using aliases that are potentially hidden by other entities.

\[
\text{qualified-alias-member:} \\
\text{identifier :: identifier type-argument-list}_\text{opt}
\]
A **qualified-alias-member** can be used as a *namespace-or-type-name* (§10.8) or as the left operand in a *member-access* (§14.5.4).

A **qualified-alias-member** consists of two identifiers, referred to as the left-hand and right-hand identifiers, separated by the :: token and optionally followed by a *type-argument-list*. When the left-hand identifier is `global` then the global namespace is searched for the right-hand identifier. For any other left-hand identifier, that identifier is looked up as an extern or using alias (§16.3 and §16.4.1). A compile-time error occurs if there is no such alias or the alias references a type. If the alias references a namespace then that namespace is searched for the right-hand identifier.

A **qualified-alias-member** has one of two forms:

- `A::B<\text{G}_1, \ldots, \text{G}_N>`, where `A` and `B` represent identifiers, and `<\text{G}_1, \ldots, \text{G}_N>` is a type argument list. (N is always at least one.)
- `A::B`, where `A` and `B` represent identifiers. (In this case, N is considered to be zero.)

Using this notation, the meaning of a **qualified-alias-member** is determined as follows:

- If `A` is the identifier `global`, then the global namespace is searched for `B`:
  - If the global namespace contains a namespace named `B` and N is zero, then the **qualified-alias-member** refers to that namespace.
  - Otherwise, if the global namespace contains a non-generic type named `B` and N is zero, then the **qualified-alias-member** refers to that type.
  - Otherwise, if the global namespace contains a type named `B` that has N type parameters, then the **qualified-alias-member** refers to that type constructed with the given type arguments.
  - Otherwise, the **qualified-alias-member** is undefined and a compile-time error occurs.

- Otherwise, starting with the namespace declaration (§16.2) immediately containing the **qualified-alias-member** (if any), continuing with each enclosing namespace declaration (if any), and ending with the compilation unit containing the **qualified-alias-member**, the following steps are evaluated until an entity is located:
  - If the namespace declaration or compilation unit contains a using-alias-directive that associates `A` with a type, then the **qualified-alias-member** is undefined and a compile-time error occurs.
  - Otherwise, if the namespace declaration or compilation unit contains an extern-alias-directive or using-alias-directive that associates `A` with a namespace, then:
    - If the namespace associated with `A` contains a namespace named `B` and N is zero, then the **qualified-alias-member** refers to that namespace.
    - Otherwise, if the namespace associated with `A` contains a non-generic type named `B` and N is zero, then the **qualified-alias-member** refers to that type.
    - Otherwise, if the namespace associated with `A` contains a type named `B` that has N type parameters, then the **qualified-alias-member** refers to that type constructed with the given type arguments.
    - Otherwise, the **qualified-alias-member** is undefined and a compile-time error occurs.

- Otherwise, the **qualified-alias-member** is undefined and a compile-time error occurs.

**Example:** In the code:

```csharp
using S = System.Net.Sockets;

class A {
    public static int x;
}
```
class C {
    public void F(int A, object S) {
        // Use global::A.x instead of A.x
        global::A.x += A;
        // Use S::Socket instead of S.Socket
        S::Socket s = S as S::Socket;
    }
}

the class A is referenced with global::A and the type System.Net.Sockets.Socket is referenced with S::Socket. Using A.x and S.Socket instead would have caused compile-time errors because A and S would have resolved to the parameters. end example

[Note: The identifier global has special meaning only when used as the left-hand identifier of a qualified-alias-name. It is not a keyword and it is not itself an alias. In the code:

    class A { }
    class C {
        global.A x;    // Error: global is not defined
        global::A y;   // Valid: References A in the global namespace
    }

using global.A causes a compile-time error since there is no entity named global in scope. If some entity named global were in scope, then global in global.A would have resolved to that entity. Using global as the left-hand identifier of a qualified-alias-member always causes a lookup in the global namespace, even if there is a using alias named global. [Example: In the code:

        using global = MyGlobalTypes;
        class A { }
        class C {
            global.A x;    // Valid: References MyGlobalTypes.A
            global::A y;   // Valid: References A in the global namespace
        }

global.A resolves to MyGlobalTypes.A and global::A resolves to class A in the global namespace. end note]
17. Classes

A class is a data structure that can contain data members (constants and fields), function members (methods, properties, events, indexers, operators, instance constructors, finalizers, and static constructors), and nested types. Class types support inheritance, a mechanism whereby a derived class can extend and specialize a base class.

17.1 Class declarations

A class-declaration is a type-declaration (§16.6) that declares a new class.

class-declaration:
  attributes\opt  class-modifiers\opt  partial\opt  class  identifier  type-parameter-list\opt
  class-base\opt  type-parameter-constraints-clauses\opt  class-body  ;\opt

A class-declaration consists of an optional set of attributes (§24), followed by an optional set of class-modifiers (§17.1.1), followed by an optional partial modifier (§17.1.4), followed by the keyword class and an identifier that names the class, followed by an optional type-parameter-list (§25.1.1), followed by an optional class-base specification (§17.1.1.3), followed by an optional type-parameter-constraints-clauses (§25.7), followed by a class-body (§17.1.3), optionally followed by a semicolon.

A class declaration shall not supply a type-parameter-constraints-clauses unless it also supplies a type-parameter-list.

A class declaration that supplies a type-parameter-list is a generic class declaration (§25.1).

17.1.1 Class modifiers

A class-declaration can optionally include a sequence of class modifiers:

class-modifiers:
  class-modifier
  class-modifiers  class-modifier

class-modifier:
  new
  public
  protected
  internal
  private
  abstract
  sealed
  static

It is a compile-time error for the same modifier to appear multiple times in a class declaration.

The new modifier is permitted on nested classes. It specifies that the class hides an inherited member by the same name, as described in §17.2.2. It is a compile-time error for the new modifier to appear on a class declaration that is not a nested class declaration.

The public, protected, internal, and private modifiers control the accessibility of the class. Depending on the context in which the class declaration occurs, some of these modifiers might not be permitted (§10.5.1).

When a partial type declaration (§17.1.4) includes an accessibility specification (via the public, protected, internal, and private modifiers), that specification shall agree with all other parts that
include an accessibility specification. If no part of a partial type includes an accessibility specification, the type is given the appropriate default accessibility (§10.5.1).

The abstract, sealed, and static modifiers are discussed in the following subclauses.

17.1.1.1 Abstract classes
The abstract modifier is used to indicate that a class is incomplete and that it is intended to be used only as a base class. An abstract class differs from a non-abstract class in the following ways:

- An abstract class cannot be instantiated directly, and it is a compile-time error to use the new operator on an abstract class. While it is possible to have variables and values whose compile-time types are abstract, such variables and values will necessarily either be null or contain references to instances of non-abstract classes derived from the abstract types.
- An abstract class is permitted (but not required) to contain abstract members.
- An abstract class cannot be sealed.

When a non-abstract class is derived from an abstract class, the non-abstract class shall include actual implementations of all inherited abstract members, thereby overriding those abstract members. [Example: In the following code]

```csharp
abstract class A
{
    public abstract void F();
}
abstract class B: A
{
    public void G() {}
}

class C: B
{
    public override void F() {
        // actual implementation of F
    }
}
```

the abstract class A introduces an abstract method F. Class B introduces an additional method G, but since it doesn’t provide an implementation of F, B shall also be declared abstract. Class C overrides F and provides an actual implementation. Since there are no abstract members in C, C is permitted (but not required) to be non-abstract. end example

If one or more parts of a partial type declaration (§17.1.4) of a class include the abstract modifier, the class is abstract. Otherwise, the class is non-abstract.

17.1.1.2 Sealed classes
The sealed modifier is used to prevent derivation from a class. A compile-time error occurs if a sealed class is specified as the base class of another class.

A sealed class cannot also be an abstract class.

[Note: The sealed modifier is primarily used to prevent unintended derivation, but it also enables certain run-time optimizations. In particular, because a sealed class is known never to have any derived classes, it is possible to transform virtual function member invocations on sealed class instances into non-virtual invocations. end note]

If one or more parts of a partial type declaration (§17.1.4) of a class include the sealed modifier, the class is sealed. Otherwise, the class is unsealed.

17.1.1.3 Static classes
When a class declaration includes a static modifier, the class being declared is said to be a static class.
A static class declaration is subject to the following restrictions:

- A static class shall not include a `sealed` or `abstract` modifier. (However, since a static class cannot be instantiated or derived from, it behaves as if it were both sealed and abstract.)

- A static class shall not include a `class-base` specification (§17.1.2) and cannot explicitly specify a base class or a list of implemented interfaces. A static class implicitly inherits from type `object`.

- A static class shall not contain any operators.

- A static class shall not have members with `protected` or `protected internal` declared accessibility.

- A static class shall only contain static members (§17.2.5). [Note: constants and nested types are classified as static members. end note]

[Example:
```
using System.Diagnostics;
public static class Precondition
{
    public sealed class Exception: System.ApplicationException
    {
        public Exception(string message) : base(message) {}
    }

    [Conditional("CHECK_PRECONDITIONS")]
    public static void Required(bool condition, string description) {
        if (!condition) {
            throw new Exception(description);
        }
    }
}
```
end example]

A static class has no instance constructors. It is not possible to declare an instance constructor in a static class, and no default instance constructor (§17.10.4) is provided for a static class.

The members of a static class are not implicitly made static; except for constants and nested types, member declarations that are intended to be static shall explicitly include a `static` modifier. When a class is nested within a static outer class, the nested class is not a static class unless it explicitly includes a `static` modifier.

A `namespace-or-type-name` (§10.8) is permitted to reference a static class if

- The `namespace-or-type-name` is the `T` in a `namespace-or-type-name` of the form `T.I`, or

- The `namespace-or-type-name` is the `T` in a `typeof-expression` (§14.5.11) of the form `typeof(T)`.

A `primary-expression` (§14.5) is permitted to reference a static class if

- The `primary-expression` is the `E` in a `member-access` (§14.5.4) of the form `E.I`.

In any other context, it is a compile-time error to reference a static class. [Note: For example, it is an error for a static class to be used as a base class, a constituent type (§17.2.4) of a member, a generic type argument, or a type parameter constraint. Likewise, a static class cannot be used in an array type, a pointer type, a `new` expression, a cast expression, an `is` expression, an `as` expression, a `sizeof` expression, or a default value expression. end note]

If one or more parts of a partial type declaration (§17.1.4) of a class include the `static` modifier, the class is static. Otherwise, the class is not static.

17.1.2 Class base specification

A class declaration can include a `class-base` specification, which defines the direct base class of the class and the interfaces (§20) implemented by the class.
17.1.2.1 Base classes
When a class is included in the class-base, it specifies the direct base class of the class being declared. If a non-partial class declaration has no class-base, or if the class-base lists only interface types, the direct base class is object. When a partial class declaration includes a base class specification, that base class specification shall reference the same type as all other parts of that partial type that include a base class specification. If no part of a partial class includes a base class specification, the base class is object. A class inherits members from its direct base class, as described in §17.2.1.

[Example: In the following code

```csharp
class A {}
class B: A {}
```

class A is said to be the direct base class of B, and B is said to be derived from A. Since A does not explicitly specify a direct base class, its direct base class is implicitly object. end example]

The base class specified in a class declaration can be a constructed class type (§25.5). A base class cannot be a type parameter on its own, though it can involve the type parameters that are in scope. [Example:

```csharp
class Extend<V>: V {}  // Error, type parameter used as base class
class C<V>: Base<V[]> {}  // Ok
```
end example]

The direct base class (and any type arguments) of a class type shall be at least as accessible as the class type itself (§10.5.4). For example, it is a compile-time error for a public class to derive from a private or internal class.

The direct base class of a class type shall not be any of the following types: System.Array, System.Delegate, System.Enum, or System.ValueType.

The base classes of a class are the direct base class and its base classes (after substituting type arguments for type parameters in constructed generic types). In other words, the set of base classes is the transitive closure of the direct base class relationship. [Note: Referring to the example above, the base classes of B are A and object. end note]

Except for class object, every class has exactly one direct base class. The object class has no direct base class and is the ultimate base class of all other classes.

When a class derives from a class A, it is a compile-time error for A to depend on B. A class directly depends on its direct base class (if any) and directly depends on the class within which it is immediately nested (if any). Given this definition, the complete set of classes upon which a class depends is the transitive closure of the directly depends on relationship.

[Example: The example

```csharp
class A: B {}
class B: C {}
class C: A {}
```

is in error because the classes circularly depend on themselves. Likewise, the example

```csharp
class A: B.C {}
```
class B: A
{
    public class C {}
}

results in a compile-time error because A depends on B.C (its direct base class), which depends on B (its immediately enclosing class), which circularly depends on A. end example

A class does not depend on the classes that are nested within it. [Example: In the following code

class A
{
    class B: A {}

} B depends on A (because A is both its direct base class and its immediately enclosing class), but A does not depend on B (since B is neither a base class nor an enclosing class of A). Thus, the example is valid. end example

It is not possible to derive from a sealed class. [Example: In the following code

sealed class A {}
class B: A {}  // Error, cannot derive from a sealed class
class B results in a compile-time error because it attempts to derive from the sealed class A. end example

17.1.2.2 Interface implementations

A class-base specification can include a list of interface types, in which case the class is said to implement the given interface types.

The set of interfaces for a type declared in multiple parts (§17.1.4) is the union of the interfaces specified on each part. A particular interface can only be named once on each part, but multiple parts can name the same base interface(s). There shall only be one implementation of each member of any given interface. [Example: In the following:

partial class C: IA, IB {...}
partial class C: IC {...}
partial class C: IA, IB {...}

the set of base interfaces for class C is IA, IB, and IC. end example]

Typically, each part provides an implementation of the interface(s) declared on that part; however, this is not a requirement. A part can provide the implementation for an interface declared on a different part. [Example:

partial class X
{
    int IComparable.CompareTo(object o) {...}
}
partial class X: IComparable
{
    ...
}
end example]

The base interfaces specified in a class declaration can be constructed interface types (§25.5). A base interface cannot be a type parameter on its own, though it can involve the type parameters that are in scope. [Example: The following code illustrates how a class can implement and extend constructed types:

class C<U, V> {}
interface I1<V> {}
class D: C<string, int>, I1<string> {}
class E<T>: C<int, T>, I1<T> {}

end example]
Interface implementations are discussed further in §20.4.

17.1.3 Class body

The class-body of a class defines the members of that class.

\[
\text{class-body:} \\
\{ \text{class-member-declarations}_{\text{opt}} \}
\]

17.1.4 Partial declarations

The modifier `partial` is used when defining a class, struct, or interface type in multiple parts. Like `get` and `set` in property accessors, `partial` is not a keyword. `partial` shall appear immediately before one of the keywords `class`, `struct`, or `interface`.

Each part of a `partial type` declaration shall include a `partial` modifier and shall be declared in the same namespace or containing type as the other parts. The `partial` modifier indicates that additional parts of the type declaration might exist elsewhere, but the existence of such additional parts is not a requirement; it is valid for the only declaration of a type to include the `partial` modifier.

All parts of a partial type shall be compiled together such that the parts can be merged at compile-time. Partial types specifically do not allow already compiled types to be extended.

Nested types can be declared in multiple parts by using the `partial` modifier. Typically, the containing type is declared using `partial` as well, and each part of the nested type is declared in a different part of the containing type.

[Example: The following partial class is implemented in two parts, which reside in different source files. The first part is machine generated by a database-mapping tool while the second part is manually authored:

```csharp
public partial class Customer
{
    private int id;
    private string name;
    private string address;
    private List<Order> orders;
    public Customer() {
    ...
    }
}

public partial class Customer
{
    public void SubmitOrder(Order orderSubmitted) {
        orders.Add(orderSubmitted);
    }
    public bool HasOutstandingOrders() {
        return orders.Count > 0;
    }
}
```

When the two parts above are compiled together, the resulting code behaves as if the class had been written as a single unit, as follows:

```csharp
public class Customer
{
    private int id;
    private string name;
    private string address;
    private List<Order> orders;
    public Customer() {
    ...
    }
```

The handling of attributes specified on the type or type parameters of different parts of a partial declaration is discussed in §24.2

### 17.2 Class members

The members of a class consist of the members introduced by its class-member-declarations and the members inherited from the direct base class.

```csharp
public void SubmitOrder(Order orderSubmitted) {
    orders.Add(orderSubmitted);
}
public bool HasOutstandingOrders() {
    return orders.Count > 0;
}
```

The members of a class are divided into the following categories:

- **Constants**, which represent constant values associated with that class (§17.3).
- **Fields**, which are the variables of that class (§17.4).
- **Methods**, both non-generic and generic, which implement the computations and actions that can be performed by that class (§17.5, §25.6).
- **Properties**, which define named characteristics and the actions associated with reading and writing those characteristics (§17.6).
- **Events**, which define notifications that can be generated by that class (§17.7).
- **Indexers**, which permit instances of that class to be indexed in the same way as arrays (§17.8).
- **Operators**, which define the expression operators that can be applied to instances of that class (§17.9).
- **Instance constructors**, which implement the actions required to initialize instances of that class (§17.10)
- **Finalizers**, which implement the actions to be performed before instances of that class are permanently discarded (§17.12).
- **Static constructors**, which implement the actions required to initialize that class itself (§17.11).
- **Types**, which represent the types that are local to that class (§16.6).

Members that can contain executable code are collectively known as the function members of the class. The function members of a class are the methods, properties, events, indexers, operators, instance constructors, finalizers, and static constructors of that class.
A class-declaration creates a new declaration space (§10.3), and the type-parameters and the class-member-declarations immediately contained by the class-declaration introduce new members into this declaration space. The following rules apply to class-member-declarations:

- Instance constructors, finalizers, and static constructors shall have the same name as the immediately enclosing class. All other members shall have names that differ from the name of the immediately enclosing class.

- The name of a type parameter in the type-parameter-list of a class declaration shall differ from the names of all other type parameters in the same type-parameter-list and shall differ from the name of the class and the names of all members of the class.

- The name of a type must differ from the names of all non-type members declared in the same class. If two or more type declarations share the same fully qualified name, the declarations must have the partial modifier (§17.1.4) and these declarations combine to define a single type. [Note: Since the fully qualified name of a type declaration encodes the number of type parameters, two distinct types may share the same name as long as they have different number of type parameters. end note]

- The name of a constant, field, property, or event shall differ from the names of all other members declared in the same class.

- The name of a method shall differ from the names of all other non-methods declared in the same class. In addition, the signature (§10.6) of a method shall differ from the signatures of all other methods declared in the same class, and two methods declared in the same class shall not have signatures that differ solely by ref and out.

- The signature of an instance constructor shall differ from the signatures of all other instance constructors declared in the same class, and two constructors declared in the same class shall not have signatures that differ solely by ref and out.

- The signature of an indexer shall differ from the signatures of all other indexers declared in the same class.

- The signature of an operator shall differ from the signatures of all other operators declared in the same class.

The inherited members of a class (§17.2.1) are not part of the declaration space of a class. [Note: Thus, a derived class is allowed to declare a member with the same name or signature as an inherited member (which in effect hides the inherited member). end note]

The set of members of a type declared in multiple parts (§17.1.4) is the union of the members declared in each part. The bodies of all parts of the type declaration share the same declaration space (§10.3), and the scope of each member (§10.7) extends to the bodies of all the parts. The accessibility domain of any member always includes all the parts of the enclosing type; a private member declared in one part is freely accessible from another part. It is a compile-time error to declare the same member in more than one part of the type, unless that member is a type having the partial modifier. [Example:

```csharp
partial class A
{
    int x;       // Error, cannot declare x more than once

    partial class Inner     // Ok, Inner is a partial type
    {
        int y;
    }
}

partial class A
{
    int x;       // Error, cannot declare x more than once
```
The ordering of members within a type declared in multiple parts is undefined. [Note: Although the ordering of members within a type is not significant to C# code, it may be significant when interfacing with other languages and environments. end note]

### 17.2.1 Inheritance

A class **inherits** the members of its direct base class. Inheritance means that a class implicitly contains all members of its direct base class, except for the instance constructors, finalizers, and static constructors of the base class. Some important aspects of inheritance are:

- **Inheritance is transitive.** If C is derived from B, and B is derived from A, then C inherits the members declared in A as well as the members declared in B.

- A derived class **extends** its direct base class. A derived class can add new members to those it inherits, but it cannot remove the definition of an inherited member.

- **Instance constructors, finalizers, and static constructors** are not inherited, but all other members are, regardless of their declared accessibility (§10.5). However, depending on their declared accessibility, inherited members might not be accessible in a derived class.

- A derived class can **hide** (§10.7.1.2) inherited members by declaring new members with the same name or signature. However, hiding an inherited member does not remove that member—it merely means that member will not be found by member lookup within the derived class.

- An instance of a class contains a set of all instance fields declared in the class and its base classes, and an implicit conversion (§13.1.4) exists from a derived class type to any of its base class types. Thus, a reference to an instance of some derived class can be treated as a reference to an instance of any of its base classes.

- A class can declare virtual methods, properties, indexers, and events, and derived classes can override the implementation of these function members. This enables classes to exhibit polymorphic behavior wherein the actions performed by a function member invocation varies depending on the run-time type of the instance through which that function member is invoked.

- Members inherited from a constructed generic type are inherited after type substitution. That is, any constituent types in the member have the base class declaration’s type parameters replaced with the corresponding type arguments used in the **class-base** specification.

[Example: In the example:

```csharp
    partial class Inner  // Ok, Inner is a partial type
    {
        int z;
    }

end example]
```
class B<T> inherits member field from A<S> after type parameter S is replaced with the type argument T[]. Similarly, class C inherits the members of B<T> (including the inherited member field) after type parameter T is replaced with the type argument string.

17.2.2 The new modifier

A class-member-declaration is permitted to declare a member with the same name or signature as an inherited member. When this occurs, the derived class member is said to hide the base class member. See §10.7.1.2 for a precise specification of when a member hides an inherited member.

An inherited member \( M \) is considered to be available if \( M \) is accessible and there is no other inherited accessible member \( N \) that already hides \( M \).

Hiding an available inherited member is not considered an error, but it does cause the compiler to issue a warning. To suppress the warning, the declaration of the derived class member can include a new modifier to indicate that the derived member is intended to hide the base member. If one or more parts of a partial declaration §17.1.4) of a nested type include the new modifier, no warning is issued if the nested type hides an available inherited member.

If a new modifier is included in a declaration that doesn’t hide an available inherited member, a warning to that effect is issued.

17.2.3 Access modifiers

A class-member-declaration can have any one of the five possible kinds of declared accessibility (§10.5.1): public, protected, internal, protected, internal, or private. Except for the protected internal combination, it is a compile-time error to specify more than one access modifier. When a class-member-declaration does not include any access modifiers, private is assumed.

17.2.4 Constituent types

Types that are used in the declaration of a member are called the constituent types of that member. Possible constituent types are the type of a constant, field, property, event, or indexer, the return type of a method or operator, and the parameter types of a method, indexer, operator, or instance constructor. The constituent types of a member shall be at least as accessible as that member itself (§10.5.4).

17.2.5 Static and instance members

Members of a class are either static members or instance members. [Note: Generally speaking, it is useful to think of static members as belonging to classes and instance members as belonging to objects (instances of classes). end note]

When a field, method, property, event, operator, or constructor declaration includes a static modifier, it declares a static member. In addition, a constant or type declaration implicitly declares a static member.

Static members have the following characteristics:

- When a static member is referenced in a member-access (§14.5.4) of the form \( E.M \), \( E \) shall denote a type that has a member \( M \). It is a compile-time error for \( E \) to denote an instance.
- A static field in a non-generic class identifies exactly one storage location. No matter how many instances of a non-generic class are created, there is only ever one copy of a static field. Each distinct closed constructed type (§25.5.2) has its own set of static fields, regardless of the number of instances of the closed constructed type.
- A static function member (method, property, event, operator, or constructor) does not operate on a specific instance, and it is a compile-time error to refer to \( this \) in such a function member.

When a field, method, property, event, indexer, constructor, or finalizer declaration does not include a static modifier, it declares an instance member. (An instance member is sometimes called a non-static member.) Instance members have the following characteristics:
• When an instance member is referenced in a member-access ($\S$14.5.4) of the form E.M, E shall denote an instance of a type that has a member M. It is a compile-time error for E to denote a type.

• Every instance of a class contains a separate set of all instance fields of the class.

• An instance function member (method, property, indexer, event, instance constructor, or finalizer) operates on a given instance of the class, and this instance can be accessed as this ($\S$14.5.7).

[Example: The following example illustrates the rules for accessing static and instance members:

class Test
{
    int x;
    static int y;
    void F() {
        x = 1;   // Ok, same as this.x = 1
        y = 1;   // Ok, same as Test.y = 1
    }
    static void G() {
        x = 1;   // Error, cannot access this.x
        y = 1;   // Ok, same as Test.y = 1
    }
    static void Main() {
        Test t = new Test();
        t.x = 1;   // Ok
        t.y = 1;   // Error, cannot access static member through instance
        Test.x = 1; // Error, cannot access instance member through type
        Test.y = 1; // Ok
    }
}

The F method shows that in an instance function member, a simple-name ($\S$14.5.2) can be used to access both instance members and static members. The G method shows that in a static function member, it is a compile-time error to access an instance member through a simple-name. The Main method shows that in a member-access ($\S$14.5.4), instance members shall be accessed through instances, and static members shall be accessed through types. end example]

17.2.6 Nested types

A type declared within a class or struct is called a nested type. A type that is declared within a compilation unit or namespace is called a non-nested type. [Example: In the following example:

using System;

class A
{
    class B
    {
        static void F() {
            Console.WriteLine("A.B.F");
        }
    }
}

class B is a nested type because it is declared within class A, and class A is a non-nested type because it is declared within a compilation unit. end example]

17.2.6.1 Fully qualified name

The fully qualified name ($\S$10.8.2) for a nested type declaration is S.N where S is the fully qualified name of the type declaration in which type N is declared and N is the unqualified name ($\S$10.8.1) of the nested type declaration (including any generic dimensionality indication).
17.2.6.2 Declared accessibility

Non-nested types can have public or internal declared accessibility and they have internal declared accessibility by default. Nested types can have these forms of declared accessibility too, plus one or more additional forms of declared accessibility, depending on whether the containing type is a class or struct:

- A nested type that is declared in a class can have any of five forms of declared accessibility (public, protected internal, protected, internal, or private) and, like other class members, defaults to private declared accessibility.
- A nested type that is declared in a struct can have any of three forms of declared accessibility (public, internal, or private) and, like other struct members, defaults to private declared accessibility.

Example: The example

```csharp
public class List
{
    // Private data structure
    private class Node
    {
        public object Data;
        public Node Next;
        public Node(object data, Node next) {
            this.Data = data;
            this.Next = next;
        }
    }
    private Node first = null;
    private Node last = null;
    // Public interface
    public void AddToFront(object o) {...}
    public void AddToBack(object o) {...}
    public object RemoveFromFront() {...}
    public object AddToFront() {...}
    public int Count { get {...} }
}
```

declares a private nested class `Node`. end example]

17.2.6.3 Hiding

A nested type can hide (§10.7.1.1) a base member. The `new` modifier (§17.2.2) is permitted on nested type declarations so that hiding can be expressed explicitly. [Example: The example

```csharp
using System;

class Base
{
    public static void M() {
        Console.WriteLine("Base.M");
    }
}

class Derived: Base
{
    new public class M
    {
        public static void F() {
            Console.WriteLine("Derived.M.F");
        }
    }
}

class Test
{
    static void Main() {
        Derived.M.F();
    }
}
```
17.2.6.4 this access

A nested type and its containing type do not have a special relationship with regard to this-access (§14.5.7). Specifically, this within a nested type cannot be used to refer to instance members of the containing type. In cases where a nested type needs access to the instance members of its containing type, access can be provided by providing the this for the instance of the containing type as a constructor argument for the nested type. [Example: The following example

```csharp
using System;
class C
{
    int i = 123;
    public void F()
    {
        Nested n = new Nested(this);
        n.G();
    }
    public class Nested
    {
        C this_c;
        public Nested(C c)
        {
            this_c = c;
        }
        public void G()
        {
            Console.WriteLine(this_c.i);
        }
    }
}
class Test
{
    static void Main()
    {
        C c = new C();
        c.F();
    }
}
```

shows this technique. An instance of C creates an instance of Nested, and passes its own this to Nested's constructor in order to provide subsequent access to C's instance members. end example]

17.2.6.5 Access to private and protected members of the containing type

A nested type has access to all of the members that are accessible to its containing type, including members of the containing type that have private and protected declared accessibility. [Example: The example

```csharp
using System;
class C
{
    private static void F()
    {
        Console.WriteLine("C.F");
    }
    public class Nested
    {
        public static void G()
        {
            F();
        }
    }
}
class Test
{
    static void Main()
    {
        C.Nested.G();
    }
}
```
shows a class C that contains a nested class Nested. Within Nested, the method G calls the static method F defined in C, and F has private declared accessibility. end example]

A nested type also can access protected members defined in a base type of its containing type. [Example: In the following code

```csharp
using System;

class Base
{
    protected void F() {
        Console.WriteLine("Base.F");
    }
}
class Derived: Base
{
    public class Nested
    {
        public void G() {
            Derived d = new Derived();
            d.F();  // ok
        }
    }
}
class Test
{
    static void Main() {
        Derived.Nested n = new Derived.Nested();
        n.G();
    }
}
```

the nested class Derived.Nested accesses the protected method F defined in Derived's base class, Base, by calling through an instance of Derived. end example]

17.2.7 Reserved member names

To facilitate the underlying C# runtime implementation, for each source member declaration that is a property, event, or indexer, the implementation shall reserve two method signatures based on the kind of the member declaration, its name, and its type (§17.2.7.1, §17.2.7.2, §17.2.7.3). It is a compile-time error for a program to declare a member whose signature matches one of these reserved signatures, even if the underlying runtime implementation does not make use of these reservations.

The reserved names do not introduce declarations, thus they do not participate in member lookup. However, a declaration’s associated reserved method signatures do participate in inheritance (§17.2.1), and can be hidden with the new modifier (§17.2.2).

[Note: The reservation of these names serves three purposes:

1. To allow the underlying implementation to use an ordinary identifier as a method name for get or set access to the C# language feature.
2. To allow other languages to interoperate using an ordinary identifier as a method name for get or set access to the C# language feature.
3. To help ensure that the source accepted by one conforming compiler is accepted by another, by making the specifics of reserved member names consistent across all C# implementations.

end note]

The declaration of a finalizer (§17.12) also causes a signature to be reserved (§17.2.7.4).

17.2.7.1 Member names reserved for properties

For a property P (§17.6) of type T, the following signatures are reserved:
T get_P();
void set_P(T value);

Both signatures are reserved, even if the property is read-only or write-only.

[Example: In the following code

```csharp
using System;

class A
{
    public int P {
        get { return 123; }
    }
}
class B: A
{
    new public int get_P() {
        return 456;
    }
    new public void set_P(int value) {
    }
}
class Test
{
    static void Main() {
        B b = new B();
        A a = b;
        Console.WriteLine(a.P);
        Console.WriteLine(b.P);
        Console.WriteLine(b.get_P());
    }
}
```

] a class A defines a read-only property P, thus reserving signatures for get_P and set_P methods. A class B derives from A and hides both of these reserved signatures. The example produces the output:

```
123
123
456
```

end example]

17.2.7.2 Member names reserved for events

For an event E (§17.7) of delegate type T, the following signatures are reserved:

```csharp
void add_E(T handler);
void remove_E(T handler);
```

17.2.7.3 Member names reserved for indexers

For an indexer (§17.8) of type T with parameter-list L, the following signatures are reserved:

```csharp
T get_Item(L);
void set_Item(L, T value);
```

Both signatures are reserved, even if the indexer is read-only or write-only.

17.2.7.4 Member names reserved for finalizers

For a class containing a finalizer (§17.12), the following signature is reserved:

```csharp
void Finalize();
```

17.3 Constants

A `constant` is a class member that represents a constant value: a value that can be computed at compile-time. A `constant-declaration` introduces one or more constants of a given type.
constant-declaration:
    attributes_{opt} constant-modifiers_{opt} const type constant-declarators ;
constant-modifiers:
    constant-modifier
    constant-modifiers constant-modifier
constant-modifier:
    new
    public
    protected
    internal
    private
constant-declarators:
    constant-declarator
    constant-declarators , constant-declarator
constant-declarator:
    identifier = constant-expression

A constant-declaration can include a set of attributes (§24), a new modifier (§17.2.2), and a valid combination of the four access modifiers (§17.2.3). The attributes and modifiers apply to all of the members declared by the constant-declaration. Even though constants are considered static members, a constant-declaration neither requires nor allows a static modifier. It is an error for the same modifier to appear multiple times in a constant declaration.

The type of a constant-declaration specifies the type of the members introduced by the declaration. The type is followed by a list of constant-declarators, each of which introduces a new member. A constant-declarator consists of an identifier that names the member, followed by an “=” token, followed by a constant-expression (§14.16) that gives the value of the member.

The type specified in a constant declaration shall be sbyte, byte, short, ushort, int, uint, long, ulong, char, float, double, decimal, bool, string, an enum-type, or a reference-type. Each constant-expression shall yield a value of the target type or of a type that can be converted to the target type by an implicit conversion (§13.1).

The type of a constant shall be at least as accessible as the constant itself (§10.5.4).

The value of a constant is obtained in an expression using a simple-name (§14.5.2) or a member-access (§14.5.4).

A constant can itself participate in a constant-expression. Thus, a constant can be used in any construct that requires a constant-expression. [Note: Examples of such constructs include case labels, goto case statements, enum member declarations, attributes, and other constant declarations. end note]

[Note: As described in §14.16, a constant-expression is an expression that can be fully evaluated at compile-time. Since the only way to create a non-null value of a reference-type other than string is to apply the new operator, and since the new operator is not permitted in a constant-expression, the only possible value for constants of reference-types other than string is null. end note]

When a symbolic name for a constant value is desired, but when the type of that value is not permitted in a constant declaration, or when the value cannot be computed at compile-time by a constant-expression, a readonly field (§17.4.2) can be used instead. [Note: The versioning semantics of const and readonly differ (§17.4.2.2). end-note]

A constant declaration that declares multiple constants is equivalent to multiple declarations of single constants with the same attributes, modifiers, and type. [Example:

```c#
    class A
    {
        public const double X = 1.0, Y = 2.0, Z = 3.0;
    }
```
is equivalent to

```csharp
class A
{
    public const double X = 1.0;
    public const double Y = 2.0;
    public const double Z = 3.0;
}
```

Constants are permitted to depend on other constants within the same program as long as the dependencies are not of a circular nature. The compiler automatically arranges to evaluate the constant declarations in the appropriate order. [Example: In the following code]

```csharp
class A
{
    public const int X = B.Z + 1;
    public const int Y = 10;
}
class B
{
    public const int Z = A.Y + 1;
}
```

the compiler first evaluates A.Y, then evaluates B.Z, and finally evaluates A.X, producing the values 10, 11, and 12. [end example] Constant declarations can depend on constants from other programs, but such dependencies are only possible in one direction. [Example: Referring to the example above, if A and B were declared in separate programs, it would be possible for A.X to depend on B.Z, but B.Z could then not simultaneously depend on A.Y. [end example]

### 17.4 Fields

A **field** is a member that represents a variable associated with an object or class. A **field-declaration** introduces one or more fields of a given type.

```plaintext
field-declaration:
    attributesopt   field-modifiersopt   type   variable-declarators   ;

field-modifiers:
    field-modifier
    field-modifiers   field-modifier

field-modifier:
    new
    public
    protected
    internal
    private
    static
    readonly
    volatile

variable-declarators:
    variable-declarator
    variable-declarators   ,   variable-declarator

variable-declarator:
    identifier
    identifier   =   variable-initializer

variable-initializer:
    expression
    array-initializer
```
A **field-declaration** can include a set of **attributes** (§24), a new modifier (§17.2.2), a valid combination of the four access modifiers (§17.2.3), and a **static** modifier (§17.4.1). In addition, a **field-declaration** can include a **readonly** modifier (§17.4.2) or a **volatile** modifier (§17.4.3), but not both. The attributes and modifiers apply to all of the members declared by the **field-declaration**. It is an error for the same modifier to appear multiple times in a **field declaration**.

The **type** of a **field-declaration** specifies the type of the members introduced by the declaration. The type is followed by a list of **variable-declarators**, each of which introduces a new member. A **variable-declarator** consists of an **identifier** that names that member, optionally followed by an “=” token and a **variable-initializer** (§17.4.5) that gives the initial value of that member.

The **type** of a field shall be at least as accessible as the field itself (§10.5.4).

The value of a field is obtained in an expression using a **simple-name** (§14.5.2) or a **member-access** (§14.5.4). The value of a non-readonly field is modified using an **assignment** (§14.14). The value of a non-readonly field can be both obtained and modified using postfix increment and decrement operators (§14.5.9) and prefix increment and decrement operators (§14.6.5).

A field declaration that declares multiple fields is equivalent to multiple declarations of single fields with the same attributes, modifiers, and type. [Example:

```csharp
class A
{
    public static int X = 1, Y, Z = 100;
}
```

is equivalent to

```csharp
class A
{
    public static int X = 1;
    public static int Y;
    public static int Z = 100;
}
```

end example]

### 17.4.1 Static and instance fields

When a field declaration includes a **static** modifier, the fields introduced by the declaration are **static fields**. When no **static** modifier is present, the fields introduced by the declaration are **instance fields**. Static fields and instance fields are two of the several kinds of variables (§12) supported by C#, and at times they are referred to as **static variables** and **instance variables**, respectively.

As explained in §17.2.5, each instance of a class contains a complete set of the instance fields of the class, while there is only one set of static fields for each non-generic class or closed constructed type, regardless of the number of instances of the class or closed constructed type.

### 17.4.2 Readonly fields

When a **field-declaration** includes a **readonly** modifier, the fields introduced by the declaration are **readonly fields**. Direct assignments to readonly fields can only occur as part of that declaration or in an instance constructor or static constructor in the same class. (A readonly field can be assigned to multiple times in these contexts.) Specifically, direct assignments to a **readonly** field are permitted only in the following contexts:

- In the **variable-declarator** that introduces the field (by including a **variable-initializer** in the declaration).
- For an instance field, in the instance constructors of the class that contains the field declaration; for a static field, in the static constructor of the class that contains the field declaration. These are also the only contexts in which it is valid to pass a **readonly** field as an **out** or **ref** parameter.
Attempting to assign to a `readonly` field or pass it as an `out` or `ref` parameter in any other context is a compile-time error.

17.4.2.1 Using static readonly fields for constants

A static `readonly` field is useful when a symbolic name for a constant value is desired, but when the type of the value is not permitted in a `const` declaration, or when the value cannot be computed at compile-time. [Example: In the following code]

```csharp
public class Color
{
    public static readonly Color Black = new Color(0, 0, 0);
    public static readonly Color White = new Color(255, 255, 255);
    public static readonly Color Red = new Color(255, 0, 0);
    public static readonly Color Green = new Color(0, 255, 0);
    public static readonly Color Blue = new Color(0, 0, 255);

    private byte red, green, blue;
    public Color(byte r, byte g, byte b) {
        red = r;
        green = g;
        blue = b;
    }
}
```

the `Black`, `White`, `Red`, `Green`, and `Blue` members cannot be declared as `const` members because their values cannot be computed at compile-time. However, declaring them `static readonly` instead has much the same effect. [end example]

17.4.2.2 Versioning of constants and static readonly fields

Constants and readonly fields have different binary versioning semantics. When an expression references a constant, the value of the constant is obtained at compile-time, but when an expression references a readonly field, the value of the field is not obtained until run-time. [Example: Consider an application that consists of two separate programs:]

```csharp
namespace Program1
{
    public class Utils
    {
        public static readonly int X = 1;
    }
}
```

and

```csharp
using System;
namespace Program2
{
    class Test
    {
        static void Main() {
            Console.WriteLine(Program1.Utils.X);
        }
    }
}
```

The `Program1` and `Program2` namespaces denote two programs that are compiled separately. Because `Program1.Utils.X` is declared as a static readonly field, the value output by the `Console.WriteLine` statement is not known at compile-time, but rather is obtained at run-time. Thus, if the value of `X` is changed and `Program1` is recompiled, the `Console.WriteLine` statement will output the new value even if `Program2` isn't recompiled. However, had `X` been a constant, the value of `X` would have been obtained at the time `Program2` was compiled, and would remain unaffected by changes in `Program1` until `Program2` is recompiled. [end example]
17.4.3 Volatile fields

When a field-declaration includes a volatile modifier, the fields introduced by that declaration are volatile fields. For non-volatile fields, optimization techniques that reorder instructions can lead to unexpected and unpredictable results in multi-threaded programs that access fields without synchronization such as that provided by the lock-statement (§15.12). These optimizations can be performed by the compiler, by the runtime system, or by hardware. For volatile fields, such reordering optimizations are restricted:

- A read of a volatile field is called a volatile read. A volatile read has “acquire semantics”; that is, it is guaranteed to occur prior to any references to memory that occur after it in the instruction sequence.
- A write of a volatile field is called a volatile write. A volatile write has “release semantics”; that is, it is guaranteed to happen after any memory references prior to the write instruction in the instruction sequence.

These restrictions ensure that all threads will observe volatile writes performed by any other thread in the order in which they were performed. A conforming implementation is not required to provide a single total ordering of volatile writes as seen from all threads of execution. The type of a volatile field shall be one of the following:

- A reference-type.
- A type-parameter that is known to be a reference type (§25.7).
- The type byte, sbyte, short, ushort, int, uint, char, float, or bool.
- An enum-type having an enum base type of byte, sbyte, short, ushort, int, uint, or ulong.

[Example: The example

```csharp
using System;
using System.Threading;

class Test
{
    public static int result;
    public static volatile bool finished;
    static void Thread2() {
        result = 143;
        finished = true;
    }
    static void Main() {
        finished = false;
        // Run Thread2() in a new thread
        new Thread(new ThreadStart(Thread2)).Start();
        // Wait for Thread2 to signal that it has a result by setting
        // finished to true.
        for (;;) {
            if (finished) {
                Console.WriteLine("result = {0}", result);
                return;
            }
        }
    }
}
```

produces the output:

`result = 143`

In this example, the method Main starts a new thread that runs the method Thread2. This method stores a value into a non-volatile field called result, then stores true in the volatile field finished. The main thread waits for the thread finished to be set to true, then reads the field result. Since finished has been declared volatile, the main thread shall read the value 143 from the field result. If the field finished had not been declared volatile, then it would be permissible for the store to result to be visible to the main thread after the store to finished, and hence for the main thread to read the value 0.
17.4.4 Field initialization

The initial value of a field, whether it be a static field or an instance field, is the default value (§12.2) of the field’s type. It is not possible to observe the value of a field before this default initialization has occurred, and a field is thus never “uninitialized”. [Example: The example

```csharp
using System;
class Test
{
    static bool b;
    int i;
    static void Main()
    {
        Test t = new Test();
        Console.WriteLine("b = {0}, i = {1}", b, t.i);
    }
}
```

produces the output

```
b = False, i = 0
```

because b and i are both automatically initialized to default values. end example]

17.4.5 Variable initializers

Field declarations can include variable-initializers. For static fields, variable initializers correspond to assignment statements that are executed during class initialization. For instance fields, variable initializers correspond to assignment statements that are executed when an instance of the class is created.

[Example: The example

```csharp
using System;
class Test
{
    static double x = Math.Sqrt(2.0);
    int i = 100;
    string s = "Hello";
    static void Main()
    {
        Test a = new Test();
        Console.WriteLine("x = {0}, i = {1}, s = {2}", x, a.i, a.s);
    }
}
```

produces the output

```
x = 1.4142135623731, i = 100, s = Hello
```

because an assignment to x occurs when static field initializers execute and assignments to i and s occur when the instance field initializers execute. end example]

The default value initialization described in §17.4.3 occurs for all fields, including fields that have variable initializers. Thus, when a class is initialized, all static fields in that class are first initialized to their default values, and then the static field initializers are executed in textual order. Likewise, when an instance of a class is created, all instance fields in that instance are first initialized to their default values, and then the instance field initializers are executed in textual order. When there are field declarations in multiple partial type declarations for the same type, the order of the parts is unspecified. However, within each part the field initializers are executed in order.

It is possible for static fields with variable initializers to be observed in their default value state. [Example: However, this is strongly discouraged as a matter of style. The example

```csharp
using System;
```
class Test
{
    static int a = b + 1;
    static int b = a + 1;
    static void Main() {
        Console.WriteLine("a = {0}, b = {1}", a, b);
    }
}

exhibits this behavior. Despite the circular definitions of a and b, the program is valid. It results in the output

    a = 1, b = 2

because the static fields a and b are initialized to 0 (the default value for int) before their initializers are
executed. When the initializer for a runs, the value of b is zero, and so a is initialized to 1. When the
initializer for b runs, the value of a is already 1, and so b is initialized to 2. end example]

17.4.5.1 Static field initialization

The static field variable initializers of a class declaration correspond to a sequence of assignments that are
executed in the textual order in which they appear in the class declaration. If a static constructor (§17.11)
exists in the class, execution of the static field initializers occurs immediately prior to executing that static
constructor. Otherwise, the static field initializers are executed at an implementation-dependent time prior to
the first use of a static field of that class. [Example: The example

    using System;
    class Test
    {
        static void Main() {
            Console.WriteLine("{0} {1}", B.Y, A.X);
        }
        public static int f(string s) {
            Console.WriteLine(s);
            return 1;
        }
    }
    class A
    {
        public static int X = Test.f("Init A");
    }
    class B
    {
        public static int Y = Test.f("Init B");
    }

might produce either the output:

    Init A
    Init B
    1 1

or the output:

    Init B
    Init A
    1 1

because the execution of X's initializer and Y's initializer could occur in either order; they are only
constrained to occur before the references to those fields. However, in the example:

    using System;
```csharp
class Test
{
    static void Main()
    {
        Console.WriteLine("{0} {1}", B.Y, A.X);
    }
    public static int f(string s)
    {
        Console.WriteLine(s);
        return 1;
    }
}
class A
{
    static A() {}
    public static int X = Test.f("Init A");
}
class B
{
    static B() {}
    public static int Y = Test.f("Init B");
}
```

the output shall be:
```
Init B
Init A
1 1
```

because the rules for when static constructors execute provide that B's static constructor (and hence B's static field initializers) shall run before A's static constructor and field initializers. *end example*

17.4.5.2 Instance field initialization

The instance field variable initializers of a class correspond to a sequence of assignments that are executed immediately upon entry to any one of the instance constructors (§17.10.2) of that class. The variable initializers are executed in the textual order in which they appear in the class declaration. The class instance creation and initialization process is described further in §17.10.

A variable initializer for an instance field cannot reference the instance being created. Thus, it is a compile-time error to reference `this` in a variable initializer, as it is a compile-time error for a variable initializer to reference any instance member through a `simple-name`. *Example: In the following code*
```
class A
{
    int x = 1;
    int y = x + 1;  // Error, reference to instance member of this
}
```
the variable initializer for `y` results in a compile-time error because it references a member of the instance being created. *end example*

17.5 Methods

A **method** is a member that implements a computation or action that can be performed by an object or class. Methods are declared using **method-declarations**:
```
method-declaration:
    method-header  method-body

method-header:
    (            formal-parameter-listopt         )    type-parameter-constraints-clausesopt

method-modifiers:
    method-modifier
    method-modifiers  method-modifier
```
C# LANGUAGE SPECIFICATION

method-modifier:
   new
   public
   protected
   internal
   private
   static
   virtual
   sealed
   override
   abstract
   extern

return-type:
   type
   void

member-name:
   identifier
   interface-type . identifier

method-body:
   block
   ;

The member-name specifies the name of the method. Unless the method is an explicit interface member implementation (§20.4.1), the member-name is simply an identifier. For an explicit interface member implementation, the member-name consists of an interface-type followed by a “.” and an identifier.

A method-declaration can include a set of attributes (§24) and a valid combination of the four access modifiers (§17.2.3), the new (§17.2.2), static (§17.5.2), virtual (§17.5.3), override (§17.5.4), sealed (§17.5.5), abstract (§17.5.6), and extern (§17.5.7) modifiers.

A declaration has a valid combination of modifiers if all of the following are true:

- The declaration includes a valid combination of access modifiers (§17.2.3).
- The declaration does not include the same modifier multiple times.
- The declaration includes at most one of the following modifiers: static, virtual, and override.
- The declaration includes at most one of the following modifiers: new and override.
- If the declaration includes the abstract modifier, then the declaration does not include any of the following modifiers: static, virtual, sealed, or extern.
- If the declaration includes the private modifier, then the declaration does not include any of the following modifiers: virtual, override, or abstract.
- If the declaration includes the sealed modifier, then the declaration also includes the override modifier.
- If the declaration is an explicit interface member implementation (indicated by a member-name including an interface-type, §20.4.1), then the declaration includes no modifiers other than possibly the extern modifier.

The return-type of a method declaration specifies the type of the value computed and returned by the method. The return-type is void if the method does not return a value.

The optional type-parameter-list specifies the type parameters for a generic method. The optional type-parameter-constraints-clauses specify the constraints for the type parameters. A method-declaration shall not have type-parameter-constraints-clauses unless it also has a type-parameter-list. A method-declaration for an explicit interface member implementation shall not have any type-parameter-constraints-clauses. A
generic *method-declaration* for an explicit interface member implementation inherits any constraints from the constraints on the interface method. Similarly, a method declaration with the *override* modifier shall not have any *type-parameter-constraints-clauses* and the constraints of the method’s type parameters are inherited from the virtual method being overridden. Generic methods are fully specified in §25.6.

The optional *formal-parameter-list* specifies the parameters of the method (§17.5.1).

The *return-type* and each of the types referenced in the *formal-parameter-list* of a method shall be at least as accessible as the method itself (§10.5.4).

For *abstract* and *extern* methods, the *method-body* consists simply of a semicolon. For all other methods, the *method-body* consists of a *block*, which specifies the statements to execute when the method is invoked.

The name, the number of type parameters, and the formal parameter list of a method define the signature (§10.6) of the method. Specifically, the signature of a method consists of its name, the number of its type parameters, and the number, *parameter-modifiers*, and types of its formal parameters. The return type is not part of a method’s signature, nor are the names of the formal parameters, the names of the type parameters, or the constraints. When a formal parameter type references a type parameter of the method, the ordinal position of the type parameter (not the name of the type parameter) is used for type equivalence.

The name of a method shall differ from the names of all other non-methods declared in the same class. In addition, the signature of a method shall differ from the signatures of all other methods declared in the same class, and two methods declared in the same class shall not have signatures that differ solely by *ref* and *out*.

### 17.5.1 Method parameters

The parameters of a method, if any, are declared by the method’s *formal-parameter-list*.

```
formal-parameter-list:
  fixed-parameters
  fixed-parameters , parameter-array
  parameter-array

fixed-parameters:
  fixed-parameter
  fixed-parameters , fixed-parameter

fixed-parameter:
  attributes opt parameter-modifier opt type identifier

parameter-modifier:
  ref
  out

parameter-array:
  attributes opt params array-type identifier
```

The formal parameter list consists of one or more comma-separated parameters of which only the last can be a *parameter-array*.

A *fixed-parameter* consists of an optional set of *attributes* (§24), an optional *ref* or *out* modifier, a *type*, and an *identifier*. Each *fixed-parameter* declares a parameter of the given type with the given name.

A *parameter-array* consists of an optional set of *attributes* (§24), a *params* modifier, an *array-type*, and an *identifier*. A parameter array declares a single parameter of the given array type with the given name. The *array-type* of a parameter array shall be a single-dimensional array type (§19.1). In a method invocation, a parameter array permits either a single argument of the given array type to be specified, or it permits zero or more arguments of the array element type to be specified. Parameter arrays are described further in §17.5.1.4.
A method declaration creates a separate declaration space (§10.3) for type parameters, formal parameters, local variables, and local constants. Names are introduced into this declaration space by the type parameter list and formal parameter list of the method and by local variable declarations and by local constant declarations in the block of the method. All names in the declaration space of a method shall be unique; otherwise, a compile-time error results.

A method invocation (§14.5.5.1) creates a copy, specific to that invocation, of the formal parameters and local variables of the method, and the argument list of the invocation assigns values or variable references to the newly created formal parameters. Within the block of a method, formal parameters can be referenced by their identifiers in simple-name expressions (§14.5.2).

There are four kinds of formal parameters:

- Value parameters, which are declared without any modifiers.
- Reference parameters, which are declared with the ref modifier.
- Output parameters, which are declared with the out modifier.
- Parameter arrays, which are declared with the params modifier.

[Note: As described in §10.6, the ref and out modifiers are part of a method’s signature, but the params modifier is not. end note]

17.5.1.1 Value parameters

A parameter declared with no modifiers is a value parameter. A value parameter corresponds to a local variable that gets its initial value from the corresponding argument supplied in the method invocation. When a formal parameter is a value parameter, the corresponding argument in a method invocation shall be an expression of a type that is implicitly convertible (§13.1) to the formal parameter type.

A method is permitted to assign new values to a value parameter. Such assignments only affect the local storage location represented by the value parameter—they have no effect on the actual argument given in the method invocation.

17.5.1.2 Reference parameters

A parameter declared with a ref modifier is a reference parameter. Unlike a value parameter, a reference parameter does not create a new storage location. Instead, a reference parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is a reference parameter, the corresponding argument in a method invocation shall consist of the keyword ref followed by a variable-reference (§12.3.3.27) of the same type as the formal parameter. A variable shall be definitely assigned before it can be passed as a reference parameter. Within a method, a reference parameter is always considered definitely assigned.

[Example: The example

```csharp
using System;

class Test
{
    static void Swap(ref int x, ref int y) {
        int temp = x;
        x = y;
        y = temp;
    }

    static void Main() {
        int i = 1, j = 2;
        Swap(ref i, ref j);
        Console.WriteLine("i = {0}, j = {1}", i, j);
    }
}
```]
produces the output
\[ i = 2, \ j = 1 \]
For the invocation of `Swap` in `Main`, `x` represents `i` and `y` represents `j`. Thus, the invocation has the effect of swapping the values of `i` and `j`. [end example]

In a method that takes reference parameters, it is possible for multiple names to represent the same storage location. [Example: In the following code

```csharp
class A
{
    string s;
    void F(ref string a, ref string b) {
        s = "One";
        a = "Two";
        b = "Three";
    }
    void G() {
        F(ref s, ref s);
    }
}
```
the invocation of `F` in `G` passes a reference to `s` for both `a` and `b`. Thus, for that invocation, the names `s`, `a`, and `b` all refer to the same storage location, and the three assignments all modify the instance field `s`. [end example]

17.5.1.3 Output parameters
A parameter declared with an `out` modifier is an output parameter. Similar to a reference parameter, an output parameter does not create a new storage location. Instead, an output parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is an output parameter, the corresponding argument in a method invocation shall consist of the keyword `out` followed by a variable-reference (§12.3.3.27) of the same type as the formal parameter. A variable need not be definitely assigned before it can be passed as an output parameter, but following an invocation where a variable was passed as an output parameter, the variable is considered definitely assigned.

Within a method, just like a local variable, an output parameter is initially considered unassigned and shall be definitely assigned before its value is used.

Every output parameter of a method shall be definitely assigned before the method returns.

Output parameters are typically used in methods that produce multiple return values. [Example:

```csharp
using System;
class Test
{
    static void SplitPath(string path, out string dir, out string name) {
        int i = path.Length;
        while (i > 0) {
            char ch = path[i - 1];
            if (ch == '\' || ch == '/' || ch == ':') break;
            i--;
        }
        dir = path.Substring(0, i);
        name = path.Substring(i);
    }
    static void Main() {
        string dir, name;
        SplitPath("c:\Windows\System\hello.txt", out dir, out name);
        Console.WriteLine(dir);
        Console.WriteLine(name);
    }
}
```
The example produces the output:

c:\Windows\System\hello.txt

Note that the dir and name variables can be unassigned before they are passed to SplitPath, and that they are considered definitely assigned following the call. end example]

17.5.1.4 Parameter arrays

A parameter declared with a params modifier is a parameter array. If a formal parameter list includes a parameter array, it shall be the last parameter in the list and it shall be of a single-dimensional array type. [Example: The types string[] and string[][] can be used as the type of a parameter array, but the type string[,] cannot. end example] It is not possible to combine the params modifier with the modifiers ref and out.

A parameter array permits arguments to be specified in one of two ways in a method invocation:

- The argument given for a parameter array can be a single expression that is implicitly convertible (§13.1) to the parameter array type. In this case, the parameter array acts precisely like a value parameter.

- Alternatively, the invocation can specify zero or more arguments for the parameter array, where each argument is an expression that is implicitly convertible (§13.1) to the element type of the parameter array. In this case, the invocation creates an instance of the parameter array type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

Except for allowing a variable number of arguments in an invocation, a parameter array is precisely equivalent to a value parameter (§17.5.1.1) of the same type. [Example: The example

```csharp
using System;

class Test {
    static void F(params int[] args) {
        Console.Write("Array contains {0} elements: ", args.Length);
        foreach (int i in args)
            Console.Write(" {0}", i);
        Console.WriteLine();
    }

    static void Main() {
        int[] arr = {1, 2, 3};
        F(arr);
        F(10, 20, 30, 40);
        F();
    }
}
```

produces the output

Array contains 3 elements: 1 2 3
Array contains 4 elements: 10 20 30 40
Array contains 0 elements:

The first invocation of F simply passes the array arr as a value parameter. The second invocation of F automatically creates a four-element int[] with the given element values and passes that array instance as a value parameter. Likewise, the third invocation of F creates a zero-element int[] and passes that instance as a value parameter. The second and third invocations are precisely equivalent to writing:

```csharp
F(new int[] {10, 20, 30, 40});
F(new int[] {});
```

end example]
When performing overload resolution, a method with a parameter array might be applicable, either in its normal form or in its expanded form (§14.4.2.1). The expanded form of a method is available only if the normal form of the method is not applicable and only if a method with the same signature as the expanded form is not already declared in the same type.

[Example: The example

```csharp
using System;

class Test
{
    static void F(params object[] a) {
        Console.WriteLine("F(object[])"奇);
    }
    static void F() {
        Console.WriteLine("F()'");
    }
    static void F(object a0, object a1) {
        Console.WriteLine("F(object,object)'");
    }
    static void Main() {
        F();
        F(1);
        F(1, 2);
        F(1, 2, 3);
        F(1, 2, 3, 4);
    }
}
```

produces the output

```
F();
F(object[]);
F(object,object);
F(object[]);
F(object[]);
```

In the example, two of the possible expanded forms of the method with a parameter array are already included in the class as regular methods. These expanded forms are therefore not considered when performing overload resolution, and the first and third method invocations thus select the regular methods. When a class declares a method with a parameter array, it is not uncommon to also include some of the expanded forms as regular methods. By doing so, it is possible to avoid the allocation of an array instance that occurs when an expanded form of a method with a parameter array is invoked. end example]

When the type of a parameter array is `object[]`, a potential ambiguity arises between the normal form of the method and the expanded form for a single `object` parameter. The reason for the ambiguity is that an `object[]` is itself implicitly convertible to type `object`. The ambiguity presents no problem, however, since it can be resolved by inserting a cast if needed.

[Example: The example

```csharp
using System;

class Test
{
    static void F(params object[] args) {
        foreach (object o in args) {
            Console.Write(o.GetType().FullName);
            Console.Write(" ");
        }
        Console.WriteLine();
    }
```
static void Main() {
    object[] a = {1, "Hello", 123.456};
    object o = a;
    F(a);
    F((object)a);
    F(o);
    F((object[])o);
}
• If R contains the introducing virtual declaration of M, then this is the most derived implementation of M.

• Otherwise, if R contains an override of M, then this is the most derived implementation of M with respect to R.

• Otherwise, the most derived implementation of M with respect to R is the same as the most derived implementation of M with respect to the direct base class of R.

[Example: The following example illustrates the differences between virtual and non-virtual methods:

```csharp
using System;

class A
{
    public void F() { Console.WriteLine("A.F"); }
    public virtual void G() { Console.WriteLine("A.G"); }
}

class B : A
{
    new public void F() { Console.WriteLine("B.F"); }
    public override void G() { Console.WriteLine("B.G"); }
}

class Test
{
    static void Main()
    {
        B b = new B();
        A a = b;
        a.F();
        b.F();
        a.G();
        b.G();
    }
}
```

In the example, A introduces a non-virtual method F and a virtual method G. The class B introduces a new non-virtual method F, thus hiding the inherited F; it also overrides the inherited method G. The example produces the output:

A.F
B.F
B.G
B.G

Notice that the statement a.G() invokes B.G, not A.G. This is because the run-time type of the instance (which is B), not the compile-time type of the instance (which is A), determines the actual method implementation to invoke. end example]

Because methods are allowed to hide inherited methods, it is possible for a class to contain several virtual methods with the same signature. This does not present an ambiguity problem, since all but the most derived method are hidden. [Example: In the following code

```csharp
using System;

class A
{
    public virtual void F() { Console.WriteLine("A.F"); }
}

class B : A
{
    public override void F() { Console.WriteLine("B.F"); }
}

class C : B
{
    new public virtual void F() { Console.WriteLine("C.F"); }
}
```
```csharp
class D: C
{
    public override void F() { Console.WriteLine("D.F"); }
}

class Test
{
    static void Main()
    {
        D d = new D();
        A a = d;
        B b = d;
        C c = d;
        a.F();
        b.F();
        c.F();
        d.F();
    }
}
```

The C and D classes contain two virtual methods with the same signature: The one introduced by A and the one introduced by C. The method introduced by C hides the method inherited from A. Thus, the override declaration in D overrides the method introduced by C, and it is not possible for D to override the method introduced by A. The example produces the output:

```
B.F
B.F
D.F
D.F
```

Note that it is possible to invoke the hidden virtual method by accessing an instance of D through a less derived type in which the method is not hidden. end example]

### 17.5.4 Override methods

When an instance method declaration includes an override modifier, the method is said to be an override method. An override method overrides an inherited virtual method with the same signature. Whereas a virtual method declaration introduces a new method, an override method declaration specializes an existing inherited virtual method by providing a new implementation of that method.

The method overridden by an override declaration is known as the overridden base method. For an override method M declared in a class C, the overridden base method is determined by examining each base class of C, starting with the direct base class of C and continuing with each successive direct base class, until an accessible method with the same signature as M is located. For the purposes of locating the overridden base method, a method is considered accessible if it is public, if it is protected, if it is protected internal, or if it is internal and declared in the same program as C.

A compile-time error occurs unless all of the following are true for an override declaration:

- An overridden base method can be located as described above.
- The overridden base method is a virtual, abstract, or override method. In other words, the overridden base method cannot be static or non-virtual.
- The overridden base method is not a sealed method.
- The override declaration and the overridden base method have the same return type.
- The override declaration and the overridden base method have the same declared accessibility. In other words, an override declaration cannot change the accessibility of the virtual method.

An override declaration can access the overridden base method using a base-access (§14.5.8). [Example: In the following code]

```csharp
class A
{
    int x;
```
```csharp
public virtual void PrintFields() {
    Console.WriteLine("x = {0}", x);
}
}
class B: A {
    int y;
    public override void PrintFields() {
        base.PrintFields();
        Console.WriteLine("y = {0}", y);
    }
}
```

the `base.PrintFields()` invocation in `B` invokes the `PrintFields` method declared in `A`. A `base-access` disables the virtual invocation mechanism and simply treats the base method as a non-virtual method. Had the invocation in `B` been written `((A)this).PrintFields()`, it would recursively invoke the `PrintFields` method declared in `B`, not the one declared in `A`, since `PrintFields` is virtual and the runtime type of `((A)this)` is `B`. end example

Only by including an `override` modifier can a method override another method. In all other cases, a method with the same signature as an inherited method simply hides the inherited method. [Example: In the following code
```csharp
class A {
    public virtual void F() {}
}
class B: A {
    public virtual void F() {}  // Warning, hiding inherited F()
}
class C: B {
    public override void F() {} // Ok, overrides A.F
}
```
the `F` method in `B` hides the virtual `F` method inherited from `A`. Rather, the `F` method in `B` hides the method in `A`, and a warning is reported because the declaration does not include a `new` modifier. end example]

[Example: In the following code
```csharp
class A {
    public virtual void F() {}
}
class B: A {
    new private void F() {}  // Hides A.F within B
}
class C: B {
    public override void F() {} // Ok, overrides A.F
}
```
the `F` method in `B` hides the virtual `F` method inherited from `A`. Since the new `F` in `B` has private access, its scope only includes the class body of `B` and does not extend to `C`. Therefore, the declaration of `F` in `C` is permitted to override the `F` inherited from `A`. end example]

### 17.5.5 Sealed methods

When an instance method declaration includes a `sealed` modifier, that method is said to be a `sealed method`. A sealed method overrides an inherited virtual method with the same signature. A sealed method shall also be marked with the `override` modifier. Use of the `sealed` modifier prevents a derived class from further overriding the method.

[Example: The example
```csharp
using System;
```
class A
{
    public virtual void F() {
        Console.WriteLine("A.F");
    }
    public virtual void G() {
        Console.WriteLine("A.G");
    }
}

class B: A
{
    public sealed override void F() {
        Console.WriteLine("B.F");
    }
    public override void G() {
        Console.WriteLine("B.G");
    }
}

class C: B
{
    public override void G() {
        Console.WriteLine("C.G");
    }
}

the class B provides two override methods: an F method that has the sealed modifier and a G method that does not. B’s use of the sealed modifier prevents C from further overriding F. end example]

17.5.6 Abstract methods

When an instance method declaration includes an abstract modifier, that method is said to be an abstract method. Although an abstract method is implicitly also a virtual method, it cannot have the modifier virtual.

An abstract method declaration introduces a new virtual method but does not provide an implementation of that method. Instead, non-abstract derived classes are required to provide their own implementation by overriding that method. Because an abstract method provides no actual implementation, the method-body of an abstract method simply consists of a semicolon.

Abstract method declarations are only permitted in abstract classes (§17.1.1.1).

[Example: In the following code

    public abstract class Shape
    {
        public abstract void Paint(Graphics g, Rectangle r);
    }

    public class Ellipse: Shape
    {
        public override void Paint(Graphics g, Rectangle r) {
            g.DrawEllipse(r);
        }
    }

    public class Box: Shape
    {
        public override void Paint(Graphics g, Rectangle r) {
            g.DrawRect(r);
        }
    }

the Shape class defines the abstract notion of a geometrical shape object that can paint itself. The Paint method is abstract because there is no meaningful default implementation. The Ellipse and Box classes are concrete Shape implementations. Because these classes are non-abstract, they are required to override the Paint method and provide an actual implementation. end example]
It is a compile-time error for a base-access (§14.5.8) to reference an abstract method. [Example: In the following code]

```csharp
abstract class A
{
    public abstract void F();
}

class B: A
{
    public override void F() {
        base.F();      // Error, base.F is abstract
    }
}
```

A compile-time error is reported for the base.F() invocation because it references an abstract method. end example]

An abstract method declaration is permitted to override a virtual method. This allows an abstract class to force re-implementation of the method in derived classes, and makes the original implementation of the method unavailable. [Example: In the following code]

```csharp
using System;
class A
{
    public virtual void F() {
        Console.WriteLine("A.F");
    }
}
abstract class B: A
{
    public abstract override void F();
}
class C: B
{
    public override void F() {
        Console.WriteLine("C.F");
    }
}
```

class A declares a virtual method, class B overrides this method with an abstract method, and class C overrides that abstract method to provide its own implementation. end example]

### 17.5.7 External methods

When a method declaration includes an extern modifier, the method is said to be an external method. External methods are implemented externally, typically using a language other than C#. Because an external method declaration provides no actual implementation, the method-body of an external method simply consists of a semicolon.

The mechanism by which linkage to an external method is achieved, is implementation-defined.

[Example: The following example demonstrates the use of the extern modifier in combination with aDllImport attribute that specifies the name of the external library in which the method is implemented:]

```csharp
using System.Text;
using System.Security.Permissions;
using System.Runtime.InteropServices;
class Path
{
    [DllImport("kernel32", SetLastError=true)]
    static extern bool CreateDirectory(string name, SecurityAttribute sa);
    [DllImport("kernel32", SetLastError=true)]
    static extern bool RemoveDirectory(string name);
}
```
17.5.8 Method body

The method-body of a method declaration consists of either a block or a semicolon.

Abstract and external method declarations do not provide a method implementation, so their method bodies simply consist of a semicolon. For any other method, the method body is a block (§15.2) that contains the statements to execute when that method is invoked.

When the return type of a method is `void`, return statements (§15.9.4) in that method’s body are not permitted to specify an expression. If execution of the method body of a void method completes normally (that is, control flows off the end of the method body), that method simply returns to its caller.

When the return type of a method is not `void`, each return statement in that method body shall specify an expression of a type that is implicitly convertible to the return type. The endpoint of the method body of a value-returning method shall not be reachable. In other words, in a value-returning method, control is not permitted to flow off the end of the method body.

[Example: In the following code]

```csharp
class A
{
    public int F() {}   // Error, return value required
    public int G() {
        return 1;
    }
    public int H(bool b) {
        if (b) {
            return 1;
        }
        else {
            return 0;
        }
    }
}
```

the value-returning `F` method results in a compile-time error because control can flow off the end of the method body. The `G` and `H` methods are correct because all possible execution paths end in a return statement that specifies a return value. end example]

17.5.9 Method overloading

The method overload resolution rules are described in §14.4.2.

17.6 Properties

A property is a member that provides access to a characteristic of an object or a class. Examples of properties include the length of a string, the size of a font, the caption of a window, the name of a customer, and so on. Properties are a natural extension of fields—both are named members with associated types, and the syntax for accessing fields and properties is the same. However, unlike fields, properties do not denote storage locations. Instead, properties have accessor that specify the statements to be executed when their values are read or written. Properties thus provide a mechanism for associating actions with the reading and writing of an object’s characteristics; furthermore, they permit such characteristics to be computed.

Properties are declared using property-declarations:
A property-declaration can include a set of attributes (§24) and a valid combination of the four access modifiers (§17.2.3), the new (§17.2.2), static (§17.6.1), virtual (§17.5.3, §17.6.3), override (§17.5.4, §17.6.3), sealed (§17.5.5), abstract (§17.5.6, §17.6.3), and extern modifiers.

Property declarations are subject to the same rules as method declarations (§17.5) with regard to valid combinations of modifiers.

The type of a property declaration specifies the type of the property introduced by the declaration, and the member-name specifies the name of the property. Unless the property is an explicit interface member implementation, the member-name is simply an identifier. For an explicit interface member implementation (§20.4.1), the member-name consists of an interface-type followed by a “.” and an identifier.

The type of a property shall be at least as accessible as the property itself (§10.5.4).

The accessor-declarations, which shall be enclosed in “{” and “}” tokens, declare the accessors (§17.6.2) of the property. The accessors specify the executable statements associated with reading and writing the property.

Even though the syntax for accessing a property is the same as that for a field, a property is not classified as a variable. Thus, it is not possible to pass a property as a ref or out argument.

When a property declaration includes an extern modifier, the property is said to be an external property. Because an external property declaration provides no actual implementation, each of its accessor-declarations consists of a semicolon.

17.6.1 Static and instance properties

When a property declaration includes a static modifier, the property is said to be a static property. When no static modifier is present, the property is said to be an instance property.

A static property is not associated with a specific instance, and it is a compile-time error to refer to this in the accessors of a static property.

An instance property is associated with a given instance of a class, and that instance can be accessed as this (§14.5.7) in the accessors of that property.

The differences between static and instance members are discussed further in §17.2.5.

17.6.2 Accessors

The accessor-declarations of a property specify the executable statements associated with reading and writing that property.
accessor-declarations:
  get-accessor-declaration set-accessor-declaration\_opt
  set-accessor-declaration get-accessor-declaration\_opt

get-accessor-declaration:
  attributes\_opt accessor-modifier\_opt get accessor-body

set-accessor-declaration:
  attributes\_opt accessor-modifier\_opt set accessor-body

accessor-modifier:
  protected
  internal
  private
  protected internal
  internal protected

accessor-body:
  block
  ;

The accessor declarations consist of a \textit{get-accessor-declaration}, a \textit{set-accessor-declaration}, or both. Each accessor declaration consists of the token \texttt{get} or \texttt{set} followed by an \textit{accessor-body}. For \texttt{abstract} and \texttt{extern} properties, the \textit{accessor-body} for each accessor specified is simply a semicolon. For the accessors of any non-abstract, non-extern property, the \textit{accessor-body} is a \texttt{block} that specifies the statements to be executed when the corresponding accessor is invoked.

A \texttt{get} accessor corresponds to a parameterless method with a return value of the property type. Except as the target of an assignment, when a property is referenced in an expression, the \texttt{get} accessor of the property is invoked to compute the value of the property (§14.1.1). The body of a \texttt{get} accessor shall conform to the rules for value-returning methods described in §17.5.8. In particular, all \texttt{return} statements in the body of a \texttt{get} accessor shall specify an expression that is implicitly convertible to the property type. Furthermore, the endpoint of a \texttt{get} accessor shall not be reachable.

A \texttt{set} accessor corresponds to a method with a single value parameter of the property type and a \texttt{void} return type. The implicit parameter of a \texttt{set} accessor is always named \texttt{value}. When a property is referenced as the target of an assignment (§14.14), or as the operand of ++ or -- (§14.5.9, 14.6.5), the \texttt{set} accessor is invoked with an argument that provides the new value (§14.14.1). The body of a \texttt{set} accessor shall conform to the rules for \texttt{void} methods described in §17.5.8. In particular, \texttt{return} statements in the \texttt{set} accessor body are not permitted to specify an expression. Since a \texttt{set} accessor implicitly has a parameter named \texttt{value}, it is a compile-time error for a local variable declaration or a local constant declaration in a \texttt{set} accessor to have that name.

Based on the presence or absence of the \texttt{get} and \texttt{set} accessors, a property is classified as follows:

- A property that includes both a \texttt{get} accessor and a \texttt{set} accessor is said to be a \textit{read-write} property.
- A property that has only a \texttt{get} accessor is said to be a \textit{read-only} property. It is a compile-time error for a read-only property to be the target of an assignment.
- A property that has only a \texttt{set} accessor is said to be a \textit{write-only} property. Except as the target of a simple assignment, it is a compile-time error to reference a write-only property in an expression. [Note: The pre- and postfix ++ and -- operators and compound assignment operators cannot be applied to write-only properties, since these operators read the old value of their operand before they write the new one. \textit{end note}]

The use of \textit{accessor-modifiers} is governed by the following restrictions:

- An \textit{accessor-modifier} cannot be used in an interface or in an explicit interface member implementation.
• For a property or indexer that has no override modifier, an accessor-modifier is permitted only if the property or indexer has both a get and set accessor, and then is permitted only on one of those accessors.

• For a property or indexer that includes an override modifier, the accessor-modifier of an accessor shall match the accessor-modifier, if any, of the accessor being overridden.

• The accessor-modifier shall declare an accessibility that is strictly more restrictive than the declared accessibility of the property or indexer itself. To be precise:
  o If the property or indexer has a declared accessibility of public, any accessor-modifier can be used.
  o If the property or indexer has a declared accessibility of protected internal, the accessor-modifier can be internal, protected, or private.
  o If the property or indexer has a declared accessibility of internal or protected, the accessor-modifier shall be private.
  o If the property or indexer has a declared accessibility of private, no accessor-modifier shall be used.

If an accessor has an accessor-modifier, the accessibility domain (§10.5.2) of the accessor is determined using the declared accessibility of the accessor-modifier. If an accessor does not have an accessor-modifier, the accessibility domain of the accessor is determined from the declared accessibility of the property or indexer.

[Example: In the following code]
```csharp
public class Button: Control
{
    private string caption;
    public string Caption {
        get {
            return caption;
        }
        set {
            if (caption != value) {
                caption = value;
                Repaint();
            }
        }
    }
    public override void Paint(Graphics g, Rectangle r) {
        // Painting code goes here
    }
}
```

the Button control declares a public Caption property. The get accessor of the Caption property returns the string stored in the private caption field. The set accessor checks if the new value is different from the current value, and if so, it stores the new value and repaints the control. Properties often follow the pattern shown above: The get accessor simply returns a value stored in a private field, and the set accessor modifies that private field and then performs any additional actions required to update fully the state of the object.

Given the Button class above, the following is an example of use of the Caption property:
```csharp
    Button okButton = new Button();
    okButton.Caption = "OK";   // Invokes set accessor
    string s = okButton.Caption;   // Invokes get accessor
```

Here, the set accessor is invoked by assigning a value to the property, and the get accessor is invoked by referencing the property in an expression. end example]

The get and set accessors of a property are not distinct members, and it is not possible to declare the accessors of a property separately. [Example: The example
class A
{
    private string name;
    public string Name {    // Error, duplicate member name
        get { return name; }
    }
    public string Name {    // Error, duplicate member name
        set { name = value; }
    }
}

does not declare a single read-write property. Rather, it declares two properties with the same name, one read-only and one write-only. Since two members declared in the same class cannot have the same name, the example causes a compile-time error to occur.

When a derived class declares a property by the same name as an inherited property, the derived property hides the inherited property with respect to both reading and writing. [Example: In the following code

class A
{
    public int P {
        set {…}
    }
}
class B: A
{
    new public int P {
        get {…}
    }
}

the P property in B hides the P property in A with respect to both reading and writing. Thus, in the statements

    B b = new B();
    b.P = 1;     // Error, B.P is read-only
    ((A)b).P = 1; // Ok, reference to A.P

the assignment to b.P causes a compile-time error to be reported, since the read-only P property in B hides the write-only P property in A. Note, however, that a cast can be used to access the hidden P property. end example]

Unlike public fields, properties provide a separation between an object’s internal state and its public interface. [Example: Consider the following:

class Label
{
    private int x, y;
    private string caption;
    public Label(int x, int y, string caption) {
        this.x = x;
        this.y = y;
        this.caption = caption;
    }
    public int X {
        get { return x; }
    }
    public int Y {
        get { return y; }
    }
    public Point Location {
        get { return new Point(x, y); }
    }
}
Here, the Label class uses two int fields, x and y, to store its location. The location is publicly exposed both as an X and a Y property and as a Location property of type Point. If, in a future version of Label, it becomes more convenient to store the location as a Point internally, the change can be made without affecting the public interface of the class:

```csharp
class Label
{
    private Point location;
    private string caption;
    public Label(int x, int y, string caption) {
        this.location = new Point(x, y);
        this.caption = caption;
    }
    public int X {
        get { return location.x; }
    }
    public int Y {
        get { return location.y; }
    }
    public Point Location {
        get { return location; }
    }
    public string Caption {
        get { return caption; }
    }
}
```

Had x and y instead been public readonly fields, it would have been impossible to make such a change to the Label class. [end example]

[Note: Exposing state through properties is not necessarily any less efficient than exposing fields directly. In particular, when a property is non-virtual and contains only a small amount of code, the execution environment might replace calls to accessors with the actual code of the accessors. This process is known as inlining, and it makes property access as efficient as field access, yet preserves the increased flexibility of properties. end note]

[Example: Since invoking a get accessor is conceptually equivalent to reading the value of a field, it is considered bad programming style for get accessors to have observable side-effects. In the example]

```csharp
class Counter
{
    private int next;
    public int Next {
        get { return next++; }
    }
}
```

the value of the Next property depends on the number of times the property has previously been accessed. Thus, accessing the property produces an observable side effect, and the property should be implemented as a method instead. [end example]

[Note: The “no side-effects” convention for get accessors doesn’t mean that get accessors should always be written simply to return values stored in fields. Indeed, get accessors often compute the value of a property by accessing multiple fields or invoking methods. However, a properly designed get accessor performs no actions that cause observable changes in the state of the object. end note]

Properties can be used to delay initialization of a resource until the moment it is first referenced. [Example:]

```csharp
using System.IO;
```
public class Console
{
    private static TextReader reader;
    private static TextWriter writer;
    private static TextWriter error;
    public static TextReader In {
        get {
            if (reader == null) {
                reader = new StreamReader(Console.OpenStandardInput());
            }
            return reader;
        }
    }
    public static TextWriter Out {
        get {
            if (writer == null) {
                writer = new StreamWriter(Console.OpenStandardOutput());
            }
            return writer;
        }
    }
    public static TextWriter Error {
        get {
            if (error == null) {
                error = new StreamWriter(Console.OpenStandardError());
            }
            return error;
        }
    }
    ...
}

The Console class contains three properties, In, Out, and Error, that represent the standard input, output, and error devices, respectively. By exposing these members as properties, the Console class can delay their initialization until they are actually used. For example, upon first referencing the Out property, as in

    Console.Out.WriteLine("hello, world");

the underlying TextWriter for the output device is created. However, if the application makes no reference to the In and Error properties, then no objects are created for those devices. end example

The presence of an accessor-modifier never affects member lookup (§14.3) or overload resolution (§14.4.2). The modifiers on the property or indexer always determine which property or indexer is bound to, regardless of the context of the access.

Once a particular property or indexer has been selected, the accessibility domains of the specific accessors involved are used to determine if that usage is valid:

- If the usage is as a value (§14.1.1), the get accessor shall exist and be accessible.
- If the usage is as the target of a simple assignment (§14.14.1), the set accessor shall exist and be accessible.
- If the usage is as the target of compound assignment (§14.14.2), or as the target of the ++ or -- operators (§14.5.9, §14.6.5), both the get accessors and the set accessor shall exist and be accessible.

[Example: In the following example, the property A.Text is hidden by the property B.Text, even in contexts where only the set accessor is called. In contrast, the property B.Count is not accessible to class M, so the accessible property A.Count is used instead.

class A
{
    public string Text {
        get { return "hello"; }
        set { }
    }
}
public int Count {
    get { return 5; }
    set { }
}
}
class B: A {
    private string text = "goodbye";
    private int count = 0;
    new public string Text {
        get { return text; }
        protected set { text = value; }
    }
    new protected int Count {
        get { return count; }
        set { count = value; }
    }
}
class M {
    static void Main() {
        B b = new B();
        b.Count = 12;   // Calls A.Count set accessor
        int i = b.Count;  // Calls A.Count get accessor
        b.Text = "howdy";  // Error, B.Text set accessor not accessible
        string s = b.Text; // Calls B.Text get accessor
    }
}
end example

An accessor that is used to implement an interface cannot have an accessor-modifier. However, if only one accessor is used to implement an interface, the other accessor can be declared with an accessor-modifier: [Example:

public interface I {
    string Prop { get; }
}
public class C: I {
    public string Prop {
        get { return "April"; } // Shall not have a modifier here
        internal set {…}   // Ok, because I.Prop has no set accessor
    }
}
end example]

17.6.3 Virtual, sealed, override, and abstract accessors

A virtual property declaration specifies that the accessors of the property are virtual. The virtual modifier applies to all non-private accessors of a property. When an accessor of a virtual property has the private accessor-modifier, the private accessor is implicitly not virtual.

An abstract property declaration specifies that the accessors of the property are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the property. Because an accessor for an abstract property declaration provides no actual implementation, its accessor-body simply consists of a semicolon. An abstract property shall not have a private accessor.

A property declaration that includes both the abstract and override modifiers specifies that the property is abstract and overrides a base property. The accessors of such a property are also abstract.
Abstract property declarations are only permitted in abstract classes (§17.1.1.1). The accessors of an inherited virtual property can be overridden in a derived class by including a property declaration that specifies an override directive. This is known as an overwriting property declaration. An overwriting property declaration does not declare a new property. Instead, it simply specializes the implementations of the accessors of an existing virtual property.

An overwriting property declaration shall specify the exact same accessibility modifiers, type, and name as the inherited property. If the inherited property has only a single accessor (i.e., if the inherited property is read-only or write-only), the overwriting property shall include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overwriting property can include either a single accessor or both accessors. If one of the inherited accessors is not accessible to the overwriting type, the overwriting property shall not include that accessor. In addition, the declared accessibility of the accessors shall match that of the overridden accessors. [Example:

```csharp
public class B
{
    public virtual int P {
        protected set {...}
        get {...}
    }
    public virtual int Q {
        private set {...} // not virtual
        get {...}
    }
}
public class D: B
{
    public override int P {
        protected set {...} // Must specify protected here
        get {...} // Must not have a modifier here
    }
    public override int Q {
        private set {...} // Error: inherited set is not accessible
        get {...} // Must not have a modifier here
    }
}
end example]

An overwriting property declaration can include the sealed modifier. Use of this modifier prevents a derived class from further overwriting the property. The accessors of a sealed property are also sealed.

Except for differences in declaration and invocation syntax, virtual, sealed, override, and abstract accessors behave exactly like virtual, sealed, override and abstract methods. Specifically, the rules described in §17.5.3, §17.5.4, §17.5.5, and §17.5.6 apply as if accessors were methods of a corresponding form:

- A get accessor corresponds to a parameterless method with a return value of the property type and the same modifiers as the containing property.
- A set accessor corresponds to a method with a single value parameter of the property type, a void return type, and the same modifiers as the containing property.

[Example: In the following code

```csharp
abstract class A
{
    int y;
    public virtual int X {
        get { return 0; }
    }
    public virtual int Y {
        get { return y; }
        set { y = value; }
    }
}
```
X is a virtual read-only property, Y is a virtual read-write property, and Z is an abstract read-write property. Because Z is abstract, the containing class A shall also be declared abstract.

A class that derives from A is shown below:

```csharp
class B : A
{
    int z;
    public override int X {
        get { return base.X + 1; }
    }
    public override int Y {
        set { base.Y = value < 0 ? 0 : value; }
    }
    public override int Z {
        get { return z; }
        set { z = value; }
    }
}
```

Here, the declarations of X, Y, and Z are overriding property declarations. Each property declaration exactly matches the accessibility modifiers, type, and name of the corresponding inherited property. The get accessor of X and the set accessor of Y use the `base` keyword to access the inherited accessors. The declaration of Z overrides both abstract accessors—thus, there are no outstanding abstract function members in B, and B is permitted to be a non-abstract class. 

**17.7 Events**

An event is a member that enables an object or class to provide notifications. Clients can attach executable code for events by supplying **event handlers**.

Events are declared using `event-declarations`:

```csharp
event-declaration:
    attributes_opt event-modifiers_opt event type variable-declarators ;
    attributes_opt event-modifiers_opt event type member-name
        { event-accessor-declarations }

event-modifiers:
    event-modifier
    event-modifiers event-modifier

event-modifier:
    new
    public
    protected
    internal
    private
    static
    virtual
    sealed
    override
    abstract
    extern

event-accessor-declarations:
    add-accessor-declaration remove-accessor-declaration
    remove-accessor-declaration add-accessor-declaration
```
add-accessor-declaration:
  attributes_opt add block

remove-accessor-declaration:
  attributes_opt remove block

An event-declaration can include a set of attributes (§24) and a valid combination of the four access modifiers (§17.2.3), the new (§17.2.2), static (§17.5.2, §17.7.3), virtual (§17.5.3, §17.7.4), override (§17.5.4, §17.7.4), sealed (§17.5.5), abstract (§17.5.6, §17.7.4), and extern modifiers.

Event declarations are subject to the same rules as method declarations (§17.5) with regard to valid combinations of modifiers.

The type of an event declaration shall be a delegate-type (§11.2), and that delegate-type shall be at least as accessible as the event itself (§10.5.4).

An event declaration can include event-accessor-declarations. However, if it does not, for non-extern, non-abstract events, the compiler shall supply them automatically (§17.7.1); for extern events, the accessors are provided externally.

An event declaration that omits event-accessor-declarations defines one or more events—one for each of the variable-declarators. The attributes and modifiers apply to all of the members declared by such an event-declaration.

It is a compile-time error for an event-declaration to include both the abstract modifier and variable-initializers or brace-delimited event-accessor-declarations.

When an event declaration includes an extern modifier, the event is said to be an external event. Because an external event declaration provides no actual implementation, it is an error for it to include both the extern modifier and event-accessor-declarations.

An event can be used as the left-hand operand of the += and -= operators removes a handler for the event (§14.14.3). These operators are used, respectively, to attach event handlers to, or to remove event handlers from an event, and the access modifiers of the event control the contexts in which such operations are permitted.

The only operations that are permitted on an event by code that is outside the type in which that event is declared, are += and -=. Therefore, while such code can add and remove handlers for an event, it cannot directly obtain or modify the underlying list of event handlers. In an operation of the form x += y or x -= y, when x is an event and the reference takes place outside the type that contains the declaration of x, the result of the operation has type void (as opposed to having the type of x, with the value of x after the assignment). This rule prohibits external code from indirectly examining the underlying delegate of an event.

[Example: The following example shows how event handlers are attached to instances of the Button class:

```csharp
public delegate void EventHandler(object sender, EventArgs e);
public class Button : Control
{
    public event EventHandler Click;
}

public class LoginDialog : Form
{
    public Button OkButton;
    public Button CancelButton;

    public LoginDialog() {
        OkButton = new Button(...);
        OkButton.Click += OkButtonClick;
        CancelButton = new Button(...);
        CancelButton.Click += CancelButtonClick;
    }
}
```
Here, the LoginDialog instance constructor creates two Button instances and attaches event handlers to the Click events. end example]

### 17.7.1 Field-like events

Within the program text of the class or struct that contains the declaration of an event, certain events can be used like fields. To be used in this way, an event shall not be abstract or extern, and shall not explicitly include event-accessor-declarations. Such an event can be used in any context that permits a field. The field contains a delegate (§22), which refers to the list of event handlers that have been added to the event. If no event handlers have been added, the field contains null.

[Example: In the following code

```csharp
public delegate void EventHandler(object sender, EventArgs e);

public class Button: Control
{
    public event EventHandler Click;
    protected void OnClick(EventArgs e) {
        EventHandler toRaise = Click;
        if (toRaise != null)
            toRaise(this, e);
    }
    public void Reset() {
        Click = null;
    }
}
```

Click is used as a field within the Button class. As the example demonstrates, the field can be examined, modified, and used in delegate invocation expressions. The OnClick method in the Button class "raises" the Click event. The notion of raising an event is precisely equivalent to invoking the delegate represented by the event—thus, there are no special language constructs for raising events. Note that the delegate invocation is preceded by a check that ensures the delegate is non-null and that the check is made on a local copy to ensure thread safety.

Outside the declaration of the Button class, the Click member can only be used on the left-hand side of the += and -= operators, as in

```csharp
b.Click += new EventHandler(...);
```

which appends a delegate to the invocation list of the Click event, and

```csharp
b.Click -= new EventHandler(...);
```

which removes a delegate from the invocation list of the Click event. end example]

When compiling a field-like event, the compiler automatically creates storage to hold the delegate, and creates accessors for the event that add or remove event handlers to the delegate field. In order to be thread-safe:

- The addition and removal operations on all instance events of a class shall be done while holding the lock (§15.12) on an object uniquely associated with the containing object (this). [Note: For example, the unique object may be the containing object itself, or a hidden instance field. end note]

- The addition and removal operations on all static events of a class shall be done while holding the lock (§15.12) on an object uniquely associated with the containing class. [Note: For example, the unique object may be the type object (§14.5.11) for the containing class, or a hidden static field. end note]
[Note: Thus, instance event declarations of the form:

```csharp
class X
{
    public event D Ev1;
    public event D Ev2;
}
```

could be compiled to:

```csharp
class X
{
    public event D Ev1 {
        add {
            lock(this) { __ev1 = __ev1 + value; }
        }
        remove {
            lock(this) { __ev1 = __ev1 - value; }
        }
    }
    public event D Ev2 {
        add {
            lock(this) { __ev2 = __ev2 + value; }
        }
        remove {
            lock(this) { __ev2 = __ev2 - value; }
        }
    }
    private D __ev1;  // field to hold a delegate
    private D __ev2;  // field to hold a delegate
}
```

or to:

```csharp
class X
{
    public event D Ev1 {
        add {
            lock(__key) { __ev1 = __ev1 + value; }
        }
        remove {
            lock(__key) { __ev1 = __ev1 - value; }
        }
    }
    public event D Ev2 {
        add {
            lock(__key) { __ev2 = __ev2 + value; }
        }
        remove {
            lock(__key) { __ev2 = __ev2 - value; }
        }
    }
    private D __ev1;  // field to hold a delegate
    private D __ev2;  // field to hold a delegate
    private readonly object __key = new object();
}
```

Similarly, static event declarations of the form:

```csharp
class X
{
    public static event D Ev1;
    public static event D Ev2;
}
```

could be compiled to:
class X
{
    public static event D Ev1
    {
        add {
            lock(typeof(X)) { __ev1 = __ev1 + value; }
        }
        remove {
            lock(typeof(X)) { __ev1 = __ev1 - value; }
        }
    }
    public static event D Ev2
    {
        add {
            lock(typeof(X)) { __ev2 = __ev2 + value; }
        }
        remove {
            lock(typeof(X)) { __ev2 = __ev2 - value; }
        }
    }
    private static D __ev1; // field to hold a delegate
    private static D __ev2; // field to hold a delegate
}

or to:

class X
{
    public static event D Ev1
    {
        add {
            lock(__key) { __ev1 = __ev1 + value; }
        }
        remove {
            lock(__key) { __ev1 = __ev1 - value; }
        }
    }
    public static event D Ev2
    {
        add {
            lock(__key) { __ev2 = __ev2 + value; }
        }
        remove {
            lock(__key) { __ev2 = __ev2 - value; }
        }
    }
    private static D __ev1; // field to hold a delegate
    private static D __ev2; // field to hold a delegate
    private static readonly object __key = new object();
}

Within class X, references to Ev1 and Ev2 are compiled to reference the hidden fields __ev1 and __ev2 instead. The names __ev1 and __ev2 are arbitrary; the hidden fields could have any name or no name at all. end note]

[Note: Access to a field-like event contained within a struct type is not thread-safe. end note]

17.7.2 Event accessors
[Note: Event declarations typically omit event-accessor-declarations, as in the Button example above. One situation for doing so involves the case in which the storage cost of one field per event is not acceptable. In such cases, a class can include event-accessor-declarations and use a private mechanism for storing the list
of event handlers. Similarly, in cases where the handling of an event requires access to external resources,
event accessors can be used to manage these resources. end note]

The event-accessor-declarations of an event specify the executable statements associated with adding and
removing event handlers.

The accessor declarations consist of an add-accessor-declaration and a remove-accessor-declaration. Each
accessor declaration consists of the token add or remove followed by a block. The block associated with an
add-accessor-declaration specifies the statements to execute when an event handler is added, and the block
associated with a remove-accessor-declaration specifies the statements to execute when an event handler is
removed.

Each add-accessor-declaration and remove-accessor-declaration corresponds to a method with a single
value parameter of the event type, and a void return type. The implicit parameter of an event accessor is
named value. When an event is used in an event assignment, the appropriate event accessor is used.
Specifically, if the assignment operator is += then the add accessor is used, and if the assignment operator is
-= then the remove accessor is used. In either case, the right-hand operand of the assignment operator is
used as the argument to the event accessor. The block of an add-accessor-declaration or a remove-accessor-
declaration shall conform to the rules for void methods described in §17.5.8. In particular, return
statements in such a block are not permitted to specify an expression.

Since an event accessor implicitly has a parameter named value, it is a compile-time error for a local
variable or constant declared in an event accessor to have that name.

[Example: In the following code

```csharp
class Control : Component
{
    // Unique keys for events
    static readonly object mouseDownEventKey = new object();
    static readonly object mouseUpEventKey = new object();
    // Return event handler associated with key
    protected Delegate GetEventHandler(object key) {...}
    // Add event handler associated with key
    protected void AddEventHandler(object key, Delegate handler) {...}
    // Remove event handler associated with key
    protected void RemoveEventHandler(object key, Delegate handler) {...}
    // MouseDown event
    public event MouseEventHandler MouseDown {
        add { AddEventHandler(mouseDownEventKey, value); }
        remove { RemoveEventHandler(mouseDownEventKey, value); }
    }
    // MouseUp event
    public event MouseEventHandler MouseUp {
        add { AddEventHandler(mouseUpEventKey, value); }
        remove { RemoveEventHandler(mouseUpEventKey, value); }
    }
    // Invoke the MouseUp event
    protected void OnMouseUp(MouseEventArgs args) {
        MouseEventHandler handler;
        handler = (MouseEventHandler)GetEventHandler(mouseUpEventKey);
        if (handler != null)
            handler(this, args);
    }
}
```

the Control class implements an internal storage mechanism for events. The AddEventHandler method
associates a delegate value with a key, the GetEventHandler method returns the delegate currently
associated with a key, and the RemoveEventHandler method removes a delegate as an event handler for
the specified event. Presumably, the underlying storage mechanism is designed such that there is no cost for
associating a null delegate value with a key, and thus unhandled events consume no storage. end example]
17.7.3 Static and instance events
When an event declaration includes a static modifier, the event is said to be a static event. When no static modifier is present, the event is said to be an instance event.

A static event is not associated with a specific instance, and it is a compile-time error to refer to this in the accessors of a static event.

An instance event is associated with a given instance of a class, and this instance can be accessed as this (§14.5.7) in the accessors of that event.

When an event is referenced in a member-access (§14.5.4) of the form E.M, if M is a static event, E shall denote a type, and if M is an instance event, E shall denote an instance.

The differences between static and instance members are discussed further in §17.2.5.

17.7.4 Virtual, sealed, override, and abstract accessors
A virtual event declaration specifies that the accessors of that event are virtual. The virtual modifier applies to both accessors of an event.

An abstract event declaration specifies that the accessors of the event are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the event. Because an accessor for an abstract event declaration provides no actual implementation, its accessor-body simply consists of a semicolon.

An event declaration that includes both the abstract and override modifiers specifies that the event is abstract and overrides a base event. The accessors of such an event are also abstract.

Abstract event declarations are only permitted in abstract classes (§17.1.1.1).

The accessors of an inherited virtual event can be overridden in a derived class by including an event declaration that specifies an override modifier. This is known as an overriding event declaration. An overriding event declaration does not declare a new event. Instead, it simply specializes the implementations of the accessors of an existing virtual event.

An overriding event declaration shall specify the exact same accessibility modifiers, type, and name as the overridden event.

An overriding event declaration can include the sealed modifier. Use of this modifier prevents a derived class from further overriding the event. The accessors of a sealed event are also sealed.

It is a compile-time error for an overriding event declaration to include a new modifier.

Except for differences in declaration and invocation syntax, virtual, sealed, override, and abstract accessors behave exactly like virtual, sealed, override and abstract methods. Specifically, the rules described in §17.5.3, §17.5.4, §17.5.5, and §17.5.6 apply as if accessors were methods of a corresponding form. Each accessor corresponds to a method with a single value parameter of the event type, a void return type, and the same modifiers as the containing event.

17.8 Indexers
An indexer is a member that enables an object to be indexed similar to an array. Indexers are declared using indexer-declarations:

```
indexer-declaration:
    attributes? indexer-modifiers? indexer-declarator { accessor-declarations }
indexer-modifiers:
    indexer-modifier
indexer-modifiers  indexer-modifier
```
indexer-modifier:
  new
  public
  protected
  internal
  private
  virtual
  sealed
  override
  abstract
  extern

indexer-declarator:
  type this [ formal-parameter-list ]
  type interface-type . this [ formal-parameter-list ]

An indexer-declaration can include a set of attributes (§24) and a valid combination of the four access modifiers (§17.2.3), the new (§17.2.2), virtual (§17.5.3), override (§17.5.4), sealed (§17.5.5), abstract (§17.5.6), and extern (§17.5.7) modifiers.

Indexer declarations are subject to the same rules as method declarations (§17.5) with regard to valid combinations of modifiers, with the one exception being that the static modifier is not permitted on an indexer declaration.

The modifiers virtual, override, and abstract are mutually exclusive except in one case. The abstract and override modifiers can be used together so that an abstract indexer can override a virtual one.

The type of an indexer declaration specifies the element type of the indexer introduced by the declaration. Unless the indexer is an explicit interface member implementation, the type is followed by the keyword this. For an explicit interface member implementation, the type is followed by an interface-type, a “.”, and the keyword this. Unlike other members, indexers do not have user-defined names.

The formal-parameter-list specifies the parameters of the indexer. The formal parameter list of an indexer corresponds to that of a method (§17.5.1), except that at least one parameter shall be specified, and that the ref and out parameter modifiers are not permitted.

The type of an indexer and each of the types referenced in the formal-parameter-list shall be at least as accessible as the indexer itself (§10.5.4).

The accessor-declarations (§17.6.2), which shall be enclosed in “{” and “}” tokens, declare the accessors of the indexer. The accessors specify the executable statements associated with reading and writing indexer elements.

Even though the syntax for accessing an indexer element is the same as that for an array element, an indexer element is not classified as a variable. Thus, it is not possible to pass an indexer element as a ref or out argument.

The formal-parameter-list of an indexer defines the signature (§10.6) of the indexer. Specifically, the signature of an indexer consists of the number and types of its formal parameters. The element type and names of the formal parameters are not part of an indexer’s signature.

The signature of an indexer shall differ from the signatures of all other indexers declared in the same class.

Indexers and properties are very similar in concept, but differ in the following ways:

- A property is identified by its name, whereas an indexer is identified by its signature.
- A property is accessed through a simple-name (§14.5.2) or a member-access (§14.5.4), whereas an indexer element is accessed through an element-access (§14.5.6.2).
- A property can be a static member, whereas an indexer is always an instance member.
• A **get** accessor of a property corresponds to a method with no parameters, whereas a **get** accessor of an indexer corresponds to a method with the same formal parameter list as the indexer.

• A **set** accessor of a property corresponds to a method with a single parameter named `value`, whereas a **set** accessor of an indexer corresponds to a method with the same formal parameter list as the indexer, plus an additional parameter named `value`.

• It is a compile-time error for an indexer accessor to declare a local variable or local constant with the same name as an indexer parameter.

• In an overriding property declaration, the inherited property is accessed using the syntax `base.P`, where `P` is the property name. In an overriding indexer declaration, the inherited indexer is accessed using the syntax `base[E]`, where `E` is a comma-separated list of expressions.

Aside from these differences, all rules defined in §17.6.2 and §17.6.3 apply to indexer accessors as well as to property accessors.

When an indexer declaration includes an `extern` modifier, the indexer is said to be an **external indexer**. Because an external indexer declaration provides no actual implementation, each of its accessor-declarations consists of a semicolon.

**Example:** The example below declares a `BitArray` class that implements an indexer for accessing the individual bits in the bit array.

```csharp
using System;
class BitArray
{
    int[] bits;
    int length;

    public BitArray(int length) {
        if (length < 0) throw new ArgumentException();
        bits = new int[((length - 1) >> 5) + 1];
        this.length = length;
    }

    public int Length {
        get { return length; }
    }

    public bool this[int index] {
        get{
            if (index < 0 || index >= length) {
                throw new IndexOutOfRangeException();
            }
            return (bits[index >> 5] & 1 << index) != 0;
        }

        set{
            if (index < 0 || index >= length) {
                throw new IndexOutOfRangeException();
            }
            if (value) {
                bits[index >> 5] |= 1 << index;
            }
            else {
                bits[index >> 5] &= ~(1 << index);
            }
        }
    }
}
```

An instance of the `BitArray` class consumes substantially less memory than a corresponding `bool[]` (since each value of the former occupies only one bit instead of the latter’s one byte), but it permits the same operations as a `bool[]`.

The following `CountPrimes` class uses a `BitArray` and the classical “sieve” algorithm to compute the number of primes between 2 and a given maximum:
class CountPrimes
{
    static int Count(int max) {
        BitArray flags = new BitArray(max + 1);
        int count = 0;
        for (int i = 2; i <= max; i++) {
            if (!flags[i]) {
                for (int j = i * 2; j <= max; j += i) flags[j] = true;
                count++;
            }
        }
        return count;
    }
    static void Main(string[] args) {
        int max = int.Parse(args[0]);
        int count = Count(max);
        Console.WriteLine(
            "Found {0} primes between 2 and {1}", count, max);
    }
}

Note that the syntax for accessing elements of the BitArray is precisely the same as for a bool[]. end example

Example: The following example shows a 26×10 grid class that has an indexer with two parameters. The first parameter is required to be an upper- or lowercase letter in the range A–Z, and the second is required to be an integer in the range 0–9.

using System;
class Grid
{
    const int NumRows = 26;
    const int NumCols = 10;
    int[,] cells = new int[NumRows, NumCols];

    public int this[char c, int colm]
    {
        get {
            c = Char.ToUpper(c);
            if (c < 'A' || c > 'Z') {
                throw new ArgumentException();
            }
            if (colm < 0 || colm >= NumCols) {
                throw new IndexOutOfRangeException();
            }
            return cells[c - 'A', colm];
        }
    }
    set {
        c = Char.ToUpper(c);
        if (c < 'A' || c > 'Z') {
            throw new ArgumentException();
        }
        if (colm < 0 || colm >= NumCols) {
            throw new IndexOutOfRangeException();
        }
        cells[c - 'A', colm] = value;
    }
}
end example

17.8.1 Indexer overloading

The indexer overload resolution rules are described in §14.4.2.
17.9 Operators

An operator is a member that defines the meaning of an expression operator that can be applied to instances of the class. Operators are declared using operator-declarations:

\[
\text{operator-declaration:} \quad \text{attributes}_{opt} \quad \text{operator-modifiers} \quad \text{operator-declarator} \quad \text{operator-body}
\]

\[
\text{operator-modifiers:} \quad \text{operator-modifier} \quad \text{operator-modifiers} \quad \text{operator-modifier}
\]

\[
\text{operator-modifier:} \quad \text{public} \quad \text{static} \quad \text{extern}
\]

\[
\text{operator-declarator:} \quad \text{unary-operat\-or-declarator} \quad \text{binary-operat\-or-declarator} \quad \text{conversion-operat\-or-declarator}
\]

\[
\text{unary-operat\-or-declarator:} \quad \text{type} \quad \text{operator} \quad \text{overloadable-unary-operat\-or} \quad (\quad \text{type} \quad \text{identifier})
\]

\[
\text{overloadable-unary-operat\-or:} \quad \text{one of}
\quad \text{+} \quad \text{-} \quad \text{!} \quad \text{~} \quad \text{++} \quad \text{--} \quad \text{true} \quad \text{false}
\]

\[
\text{binary-operat\-or-declarator:} \quad \text{type} \quad \text{operator} \quad \text{overloadable-binary-operat\-or} \quad (\quad \text{type} \quad \text{identifier}, \quad \text{type} \quad \text{identifier})
\]

\[
\text{overloadable-binary-operat\-or:} \quad \text{one of}
\quad \text{+} \quad \text{-} \quad \text{*} \quad \text{/} \quad \% \quad & \quad | \quad ^\quad \ll \quad \text{right-shift}
\quad \text{==} \quad \text{!=} \quad \text{>} \quad \text{<} \quad \text{>=} \quad \text{<=}
\]

\[
\text{conversion-operat\-or-declarator:} \quad \text{implicit} \quad \text{operator} \quad \text{type} \quad (\quad \text{type} \quad \text{identifier})
\quad \text{explicit} \quad \text{operator} \quad \text{type} \quad (\quad \text{type} \quad \text{identifier})
\]

\[
\text{operator-body:} \quad \text{block}
\quad ;
\]

There are three categories of overloadable operators: Unary operators (§17.9.1), binary operators (§17.9.2), and conversion operators (§17.9.3).

When an operator declaration includes an extern modifier, the operator is said to be an external operator. Because an external operator provides no actual implementation, its operator-body consists of a semi-colon. For all other operators, the operator-body consists of a block, which specifies the statements to execute when the operator is invoked. The block of an operator shall conform to the rules for value-returning methods described in §17.5.8.

The following rules apply to all operator declarations:

- An operator declaration shall include both a public and a static modifier.
- The parameter(s) of an operator shall be value parameters. It is a compile-time error for an operator declaration to specify ref or out parameters.
- The signature of an operator (§17.9.1, §17.9.2, §17.9.3) shall differ from the signatures of all other operators declared in the same class.
• All types referenced in an operator declaration shall be at least as accessible as the operator itself (§10.5.4).
• It is an error for the same modifier to appear multiple times in an operator declaration.

Each operator category imposes additional restrictions, as described in the following subclauses.

Like other members, operators declared in a base class are inherited by derived classes. Because operator declarations always require the class or struct in which the operator is declared to participate in the signature of the operator, it is not possible for an operator declared in a derived class to hide an operator declared in a base class. Thus, the new modifier is never required, and therefore never permitted, in an operator declaration.

Additional information on unary and binary operators can be found in §14.2.

Additional information on conversion operators can be found in §13.4.

17.9.1 Unary operators
The following rules apply to unary operator declarations, where $T$ denotes the class or struct type that contains the operator declaration:

• A unary $+$, $-$, $!$, or $~$ operator shall take a single parameter of type $T$ or $T?$ and can return any type.
• A unary $++$ or $--$ operator shall take a single parameter of type $T$ or $T?$ and shall return type that same type.
• A unary $true$ or $false$ operator shall take a single parameter of type $T$ or $T?$ and shall return type $bool$.

The signature of a unary operator consists of the operator token ($+$, $-$, $!$, $~$, $++$, $--$, $true$, or $false$) and the type of the single formal parameter. The return type is not part of a unary operator’s signature, nor is the name of the formal parameter.

The $true$ and $false$ unary operators require pair-wise declaration. A compile-time error occurs if a class declares one of these operators without also declaring the other. The $true$ and $false$ operators are described further in §14.17.

[Example: The following example shows an implementation and subsequent usage of operator++ for an integer vector class:

```csharp
public class IntVector
{
    public int Length { … } // read-only property
    public int this[int index] { … } // read-write indexer
    public IntVector(int vectorLength) { … }
    public static IntVector operator++(IntVector iv) {
        IntVector temp = new IntVector(iv.Length);
        for (int i = 0; i < iv.Length; ++i)
            temp[i] = iv[i] + 1;
        return temp;
    }
}

class Test
{
    static void Main() {
        IntVector iv1 = new IntVector(4); // vector of 4x0
        IntVector iv2;
        iv2 = iv1++; // iv2 contains 4x0, iv1 contains 4x1
        iv2 = ++iv1; // iv2 contains 4x2, iv1 contains 4x2
    }
}
```

Note how the operator method returns the value produced by adding 1 to the operand, just like the postfix increment and decrement operators (§14.5.9), and the prefix increment and decrement operators (§14.6.5).
Unlike in C++, this method need not, and, in fact, should not, modify the value of its operand directly.  

17.9.2 Binary operators
The following rules apply to binary operator declarations, where $T$ denotes the class or struct type that contains the operator declaration:

- A binary non-shift operator must take two parameters, at least one of which must have type $T$ or $T?$, and can return any type.
- A binary $<<$ or $>>$ operator (§14.8) must take two parameters, the first of which must have type $T$ or $T?$ and the second of which must have type `int`, and can return any type.

The signature of a binary operator consists of the operator token (+, -, *, /, %, &!, ^, <<, right-shift, ==, !=, >, <, >=, or <=) and the types of the two formal parameters. The return type and the names of the formal parameters are not part of a binary operator’s signature.

Certain binary operators require pair-wise declaration. For every declaration of either operator of a pair, there shall be a matching declaration of the other operator of the pair. Two operator declarations match when they have the same return type and the same type for each parameter. The following operators require pair-wise declaration:

- `operator ==` and `operator !=`
- `operator >` and `operator `<`
- `operator >=` and `operator <=`

17.9.3 Conversion operators
A conversion operator declaration introduces a user-defined conversion operator (§13.4), which augments the pre-defined implicit and explicit conversions.

A conversion operator declaration that includes the `implicit` keyword introduces a user-defined implicit conversion operator. Implicit conversions can occur in a variety of situations, including function member invocations, cast expressions, and assignments. This is described further in §13.1.

A conversion operator declaration that includes the `explicit` keyword introduces a user-defined explicit conversion operator. Explicit conversions can occur in cast expressions, and are described further in §13.2.

A conversion operator converts from a source type, indicated by the parameter type of the conversion operator, to a target type, indicated by the return type of the conversion operator. A class or struct is permitted to declare a conversion from a source type $S$ to a target type $T$ only if all of the following are true, where $S0$ and $T0$ are the types that result from removing the trailing `?` modifiers, if any, from $S$ and $T$:

- $S0$ and $T0$ are different types.
- Either $S0$ or $T0$ is the class or struct type in which the operator declaration takes place.
- Neither $S0$ nor $T0$ is an `interface-type`.
- Excluding user-defined conversions, a conversion does not exist from $S$ to $T$ or from $T$ to $S$.

From the second rule it follows that a conversion operator shall convert either to or from the class or struct type in which the operator is declared.  

[Example: It is possible for a class or struct type $C$ to define a conversion from $C$ to `int` and from `int` to $C$, but not from `int` to `bool`. end example]  

It is not possible to redefine a pre-defined conversion. Thus, conversion operators are not allowed to convert from or to `object` because implicit and explicit conversions already exist between `object` and all other types. Likewise, neither the source nor the target types of a conversion can be a base type of the other, since a conversion would then already exist.
User-defined conversions are not allowed to convert from or to interface-types. In particular, this restriction ensures that no user-defined transformations occur when converting to an interface-type, and that a conversion to an interface-type succeeds only if the object being converted actually implements the specified interface-type.

The signature of a conversion operator consists of the source type and the target type. (This is the only form of member for which the return type participates in the signature.) The implicit or explicit classification of a conversion operator is not part of the operator’s signature. Thus, a class or struct cannot declare both an implicit and an explicit conversion operator with the same source and target types.

[Note: In general, user-defined implicit conversions should be designed to never throw exceptions and never lose information. If a user-defined conversion can give rise to exceptions (for example, because the source argument is out of range) or loss of information (such as discarding high-order bits), then that conversion should be defined as an explicit conversion. end note]

[Example: In the following code]
```csharp
using System;
public struct Digit
{
    byte value;
    public Digit(int value) {
        if (value < 0 || value > 9) throw new ArgumentException();
        this.value = value;
    }
    public static implicit operator byte(Digit d) {
        return d.value;
    }
    public static explicit operator Digit(int n) {
        return new Digit(n);
    }
}
```
the conversion operator from Digit to byte is implicit because it never throws exceptions or loses information, but the conversion operator from int to Digit is explicit since Digit can only represent a subset of the possible values of an int. end example]

17.10 Instance constructors

An instance constructor is a member that implements the actions required to initialize an instance of a class. Instance constructors are declared using constructor-declarations:

```
constructor-declaration:
    attributes? constructor-modifiers? constructor-declarator constructor-body

constructor-modifiers:
    constructor-modifier
    constructor-modifiers constructor-modifier

constructor-modifier:
    public
    protected
    internal
    private
    extern

constructor-declarator:
    identifier ( formal-parameter-listopt ) constructor-initializeropt

constructor-initializer:
    : base ( argument-listopt )
    : this ( argument-listopt )
```
A constructor-declaration can include a set of attributes (§24), a valid combination of the four access modifiers (§17.2.3), and an extern (§17.5.7) modifier. A constructor declaration is not permitted to include the same modifier multiple times.

The identifier of a constructor-declarator shall name the class in which the instance constructor is declared. If any other name is specified, a compile-time error occurs.

The optional formal-parameter-list of an instance constructor is subject to the same rules as the formal-parameter-list of a method (§17.5). The formal parameter list defines the signature (§10.6) of an instance constructor and governs the process whereby overload resolution (§14.4.2) selects a particular instance constructor in an invocation.

Each of the types referenced in the formal-parameter-list of an instance constructor shall be at least as accessible as the constructor itself (§10.5.4).

The optional constructor-initializer specifies another instance constructor to invoke before executing the statements given in the constructor-body of this instance constructor. This is described further in §17.10.1.

When a constructor declaration includes an extern modifier, the constructor is said to be an external constructor.

Because an external constructor declaration provides no actual implementation, its constructor-body consists of a semicolon. For all other constructors, the constructor-body consists of a block, which specifies the statements to initialize a new instance of the class. This corresponds exactly to the block of an instance method with a void return type (§17.5.8).

Instance constructors are not inherited. Thus, a class has no instance constructors other than those actually declared in the class. If a class contains no instance constructor declarations, a default instance constructor is automatically provided (§17.10.4).

Instance constructors are invoked by object-creation-expressions (§14.5.10.1) and through constructor-initializers.

### 17.10.1 Constructor initializers

All instance constructors (except those for class object) implicitly include an invocation of another instance constructor immediately before the constructor-body. The constructor to implicitly invoke is determined by the constructor-initializer:

- An instance constructor initializer of the form base(argument-listopt) causes an instance constructor from the direct base class to be invoked. That constructor is selected using argument-list and the overload resolution rules of §14.4.2. The set of candidate instance constructors consists of all accessible instance constructors declared in the direct base class, or the default constructor (§17.10.4), if no instance constructors are declared in the direct base class. If this set is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs.

- An instance constructor initializer of the form this(argument-listopt) causes an instance constructor from the class itself to be invoked. The constructor is selected using argument-list and the overload resolution rules of §14.4.2. The set of candidate instance constructors consists of all accessible instance constructors declared in the class itself. If that set is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs. If an instance constructor declaration includes a constructor initializer that invokes the constructor itself, a compile-time error occurs.

If an instance constructor has no constructor initializer, a constructor initializer of the form base() is implicitly provided. [Note: Thus, an instance constructor declaration of the form

```c
C(...) {...
```

is exactly equivalent to

```c
C(...) {
```
The scope of the parameters given by the formal-parameter-list of an instance constructor declaration includes the constructor initializer of that declaration. Thus, a constructor initializer is permitted to access the parameters of the constructor. [Example:

```csharp
class A
{
    public A(int x, int y) {}
}
class B: A
{
    public B(int x, int y): base(x + y, x - y) {}
}
```
end example]

An instance constructor initializer cannot access the instance being created. Therefore it is a compile-time error to reference this in an argument expression of the constructor initializer, as it is a compile-time error for an argument expression to reference any instance member through a simple-name.

### 17.10.2 Instance variable initializers

When an instance constructor has no constructor initializer, or it has a constructor initializer of the form base(...), that constructor implicitly performs the initializations specified by the variable-initializers of the instance fields declared in its class. This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor and before the implicit invocation of the direct base class constructor. The variable initializers are executed in the textual order in which they appear in the class declaration (§17.4.5).

### 17.10.3 Constructor execution

Variable initializers are transformed into assignment statements, and these assignment statements are executed before the invocation of the base class instance constructor. This ordering ensures that all instance fields are initialized by their variable initializers before any statements that have access to that instance are executed. [Example:

```csharp
using System;
class A
{
    public A() {
        PrintFields();
    }
    public virtual void PrintFields() {}
}
class B: A
{
    int x = 1;
    int y;
    public B() {
        y = -1;
    }
    public override void PrintFields() {
        Console.WriteLine("x = {0}, y = {1}", x, y);
    }
}
```

When new B() is used to create an instance of B, the following output is produced:

x = 1, y = 0
The value of x is 1 because the variable initializer is executed before the base class instance constructor is invoked. However, the value of y is 0 (the default value of an int) because the assignment to y is not executed until after the base class constructor returns.

It is useful to think of instance variable initializers and constructor initializers as statements that are automatically inserted before the constructor-body. The example

```csharp
using System;
using System.Collections;

class A {
    int x = 1, y = -1, count;
    public A() {
        count = 0;
    }
    public A(int n) {
        count = n;
    }
}
class B: A {
    double sqrt2 = Math.Sqrt(2.0);
    ArrayList items = new ArrayList(100);
    int max;
    public B(): this(100) {
        items.Add("default");
    }
    public B(int n): base(n – 1) {
        max = n;
    }
}
```

contains several variable initializers; it also contains constructor initializers of both forms (base and this). The example corresponds to the code shown below, where each comment indicates an automatically inserted statement (the syntax used for the automatically inserted constructor invocations isn’t valid, but merely serves to illustrate the mechanism).

```csharp
using System.Collections;

class A {
    int x, y, count;
    public A() {
        x = 1;        // Variable initializer
        y = -1;        // Variable initializer
        object();       // Invoke object() constructor
        count = 0;
    }
    public A(int n) {
        x = 1;        // Variable initializer
        y = -1;        // Variable initializer
        object();       // Invoke object() constructor
        count = n;
    }
}
class B: A {
    double sqrt2;
    ArrayList items;
    int max;
    ```
public B(): this(100) {
    B(100);        // Invoke B(int) constructor
    items.Add("default");
}

public B(int n): base(n – 1) {
    sqrt2 = Math.Sqrt(2.0);   // Variable initializer
    items = new ArrayList(100); // Variable initializer
    A(n – 1);       // Invoke A(int) constructor
    max = n;
}

end example

17.10.4 Default constructors
If a class contains no instance constructor declarations, a default instance constructor is automatically provided. That default constructor simply invokes the parameterless constructor of the direct base class. If the direct base class does not have an accessible parameterless instance constructor, a compile-time error occurs. If the class is abstract then the declared accessibility for the default constructor is protected. Otherwise, the declared accessibility for the default constructor is public. [Note: Thus, the default constructor is always of the form

protected C(): base() {}

or

public C(): base() {}

where C is the name of the class. end note]

Example: In the following code

class Message
{
    object sender;
    string text;
}

a default constructor is provided because the class contains no instance constructor declarations. Thus, the example is precisely equivalent to

class Message
{
    object sender;
    string text;

    public Message(): base() {}
}

end example

17.10.5 Private constructors
When a class declares only private instance constructors, it is not possible for other classes (that are not nested in the class) to derive from that class or to create instances of that class. [Example: Private instance constructors can be used to restrict instantiation of the class to a prescribed set of instances. For example:

    public class Color
    {
        private byte val;

        private Color(byte val) { this.val = val; }

        public static readonly Color Red = new Color(0);
        public static readonly Color Green = new Color(1);
        public static readonly Color Blue = new Color(2);
    }

Since Color’s constructor is private, there will never be more than three instances of the Color class, namely the ones stored in the static fields and returned by the static properties. [end example]

At least one instance constructor shall be declared to suppress the automatic generation of a default constructor.

### 17.10.6 Optional instance constructor parameters

[Note: The this(...) form of constructor initializer is commonly used in conjunction with overloading to implement optional instance constructor parameters. In the example]

```java
class Text
{
    public Text(): this(0, 0, null) {}  
    public Text(int x, int y): this(x, y, null) {}  
    public Text(int x, int y, string s) {
        // Actual constructor implementation
    
    }
}
```

the first two instance constructors merely provide the default values for the missing arguments. Both use a this(...) constructor initializer to invoke the third instance constructor, which actually does the work of initializing the new instance. The effect is that of optional constructor parameters:

```java
Text t1 = new Text();     // Same as Text(0, 0, null)
Text t2 = new Text(5, 10);    // Same as Text(5, 10, null)
Text t3 = new Text(5, 20, "Hello");
```

[end note]

### 17.11 Static constructors

A static constructor is a member that implements the actions required to initialize a class. Static constructors are declared using static-constructor-declarations:

```
static-constructor-declaration: 
    attributesopt static-constructor-modifiers identifier ( ) static-constructor-body

static-constructor-modifiers: 
    externopt static

static-constructor-body: 
    block
    ;
```

A static-constructor-declaration can include a set of attributes (§24) and an extern modifier (§17.5.7).

The identifier of a static-constructor-declaration shall name the class in which the static constructor is declared. If any other name is specified, a compile-time error occurs.

When a static constructor declaration includes an extern modifier, the static constructor is said to be an external static constructor. Because an external static constructor declaration provides no actual implementation, its static-constructor-body consists of a semicolon. For all other static constructor declarations, the static-constructor-body consists of a block, which specifies the statements to execute in order to initialize the class. This corresponds exactly to the method-body of a static method with a void return type (§17.5.8).

Static constructors are not inherited, and cannot be called directly.

The static constructor for a non-generic class executes at most once in a given application domain. The static constructor for a generic class declaration executes at most once for each closed constructed type constructed from the class declaration (§25.1.5). The execution of a static constructor is triggered by the first of the following events to occur within an application domain:
• An instance of the class is created.
• Any of the static members of the class are referenced.

If a class contains the `Main` method (§10.1) in which execution begins, the static constructor for that class executes before the `Main` method is called. If a class contains any static fields with initializers, those initializers are executed in textual order immediately prior to executing the static constructor (§17.4.5).

[Example: The example
```csharp
using System;

class Test
{
    static void Main()
    {
        A.F();
        B.F();
    }
}

class A
{
    static A()
    {
        Console.WriteLine("Init A");
    }
    public static void F()
    {
        Console.WriteLine("A.F");
    }
}

class B
{
    static B()
    {
        Console.WriteLine("Init B");
    }
    public static void F()
    {
        Console.WriteLine("B.F");
    }
}
```
shall produce the output:
```
Init A
A.F
Init B
B.F
```
because the execution of `A`'s static constructor is triggered by the call to `A.F`, and the execution of `B`'s static constructor is triggered by the call to `B.F`. end example]

It is possible to construct circular dependencies that allow static fields with variable initializers to be observed in their default value state.

[Example: The example
```csharp
using System;

class A
{
    public static int X;
    static A() { X = B.Y + 1; }
}

class B
{
    public static int Y = A.X + 1;
    static B() {}
    static void Main()
    {
        Console.WriteLine("X = {0}, Y = {1}", A.X, B.Y);
    }
}
```
produces the output

\[ X = 1, \ Y = 2 \]

To execute the `Main` method, the system first runs the initializer for `B.Y`, prior to class `B`'s static constructor. `Y`'s initializer causes `A`'s static constructor to be run because the value of `A.X` is referenced. The static constructor of `A` in turn proceeds to compute the value of `X`, and in doing so fetches the default value of `Y`, which is zero. `A.X` is thus initialized to 1. The process of running `A`'s static field initializers and static constructor then completes, returning to the calculation of the initial value of `Y`, the result of which becomes 2.  

17.12 Finalizers

[Note: In the previous version of this standard, what is now referred to as a "finalizer" was called a "destructor". Experience has shown that the term "destructor" caused confusion and often resulted to incorrect expectations, especially to programmers knowing C++. In C++, a destructor is called in a determinate manner, whereas, in C#, a finalizer is not. To get determinate behavior from C#, one should use `Dispose`. end note]

A **finalizer** is a member that implements the actions required to finalize an instance of a class. A finalizer is declared using a **finalizer-declaration**:

```
finalizer-declaration:
  attributes\_opt extern\_opt ~ identifier ( ) finalizer-body

finalizer-body:
  block ;
```

A **finalizer-declaration** can include a set of **attributes** (§24).

The **identifier** of a **finalizer-declarator** shall name the class in which the finalizer is declared. If any other name is specified, a compile-time error occurs.

When a finalizer declaration includes an `extern` modifier, the finalizer is said to be an **external finalizer**. Because an external finalizer declaration provides no actual implementation, its **finalizer-body** consists of a semicolon. For all other finalizers, the **finalizer-body** consists of a **block**, which specifies the statements to execute in order to finalize an instance of the class. A **finalizer-body** corresponds exactly to the **method-body** of an instance method with a `void` return type (§17.5.8).

Finalizers are not inherited. Thus, a class has no finalizers other than the one that can be declared in that class.

[Note: Since a finalizer is required to have no parameters, it cannot be overloaded, so a class can have, at most, one finalizer. end note]

Finalizers are invoked automatically, and cannot be invoked explicitly. An instance becomes eligible for finalization when it is no longer possible for any code to use that instance. Execution of the finalizer for the instance can occur at any time after the instance becomes eligible for finalization (§10.9). When an instance is finalized, the finalizers in that instance's inheritance chain are called, in order, from most derived to least derived [Example: The output of the example

```
using System;

class A
{
  ~A() {
    Console.WriteLine("A's finalizer");
  }
}
```
class B: A {
    ~B() {
        Console.WriteLine("B's finalizer");
    }
}

class Test {
    static void Main() {
        B b = new B();
        b = null;
        GC.Collect();
        GC.WaitForPendingFinalizers();
    }
}

is
B's finalizer
A's finalizer

since finalizers in an inheritance chain are called in order, from most derived to least derived. \(\text{end example}\)

[Note: If an uncaught exception is thrown, it is unspecified whether the base class finalizer is called (§23.3). \(\text{end note}\)]

Finalizers can be implemented by overriding the virtual method \texttt{Finalize} on \texttt{System.Object}. In any event, C# programs are not permitted to override this method or call it (or overrides of it) directly. \(\text{Example:}\) For instance, the program

class A {
    protected override void Finalize() {} // error
    public void F() {
        this.Finalize(); // error
    }
}

contains two errors. \(\text{end example}\)

The compiler behaves as if \texttt{System.Object.Finalize}, and overrides of it, does not exist at all. \(\text{Example:}\) Thus, this program:

class A {
    void Finalize() {} // permitted
}

is valid and the method shown hides \texttt{System.Object}'s \texttt{Finalize} method, without requiring the \texttt{new} modifier. \(\text{end example}\)

For a discussion of the behavior when an exception is thrown from a finalizer, see §23.3.
18. Structs

Structs are similar to classes in that they represent data structures that can contain data members and function members. However, unlike classes, structs are value types and do not require heap allocation. A variable of a struct type directly contains the data of the struct, whereas a variable of a class type contains a reference to the data, the latter known as an object.

[Note: Structs are particularly useful for small data structures that have value semantics. Complex numbers, points in a coordinate system, or key-value pairs in a dictionary are all good examples of structs. Key to these data structures is that they have few data members, that they do not require use of inheritance or referential identity, and that they can be conveniently implemented using value semantics where assignment copies the value instead of the reference. end note]

As described in §11.1.4, the simple types provided by C#, such as int, double, and bool, are, in fact, all struct types. Just as these predefined types are structs, it is also possible to use structs and operator overloading to implement new “primitive” types in the C# language. Two examples of such types are given at the end of this clause (§Error! Reference source not found.).

18.1 Struct declarations

A **struct-declaration** is a **type-declaration** (§16.6) that declares a new struct:

```plaintext
struct-declaration:
  attributes_opt struct-modifiers_opt partial_opt struct identifier type-parameter-list_opt
  struct-interfaces_opt type-parameter-constraints-clauses_opt struct-body ; opt
```

A struct-declaration consists of an optional set of **attributes** (§24), followed by an optional set of **struct-modifiers** (§18.1.1), followed by an optional **partial** modifier (§17.1.4), followed by the keyword **struct** and an **identifier** that names the struct, followed by an optional **type-parameter-list** (§25.1.1), followed by an optional **struct-interfaces** specification (§18.1.2), followed by an optional **type-parameter-constraints-clauses** (§25.7), followed by a **struct-body** (§18.1.3), optionally followed by a semicolon.

A struct declaration shall not supply a **type-parameter-constraints-clauses** unless it also supplies a **type-parameter-list**.

A struct declaration that supplies a **type-parameter-list** is a generic struct declaration (§25.2).

18.1.1 Struct modifiers

A **struct-declaration** can optionally include a sequence of struct modifiers:

```plaintext
struct-modifiers:
  struct-modifier
  struct-modifiers struct-modifier
```

A **struct-modifier** can be one of:

- `new`
- `public`
- `protected`
- `internal`
- `private`

It is a compile-time error for the same modifier to appear multiple times in a struct declaration.

The modifiers of a struct declaration have the same meaning as those of a class declaration (§17.1.1).
18.1.2 Struct interfaces
A struct declaration can include a struct-interfaces specification, in which case the struct is said to implement the given interface types.

```
struct-interfaces:
  :  interface-type-list
```

The handling of interfaces on multiple parts of a partial struct declaration (§17.1.4) are discussed further in §17.1.2.2.

Interface implementations are discussed further in §20.4.

18.1.3 Struct body
The struct-body of a struct defines the members of the struct.

```
struct-body:
  {  struct-member-declarations_opt  }
```

18.2 Struct members
The members of a struct consist of the members introduced by its struct-member-declarations and the members inherited from the type System.ValueType.

```
struct-member-declarations:
  struct-member-declaration
  struct-member-declarations  struct-member-declaration

struct-member-declaration:
  constant-declaration
  field-declaration
  method-declaration
  property-declaration
  event-declaration
  indexer-declaration
  operator-declaration
  constructor-declaration
  static-constructor-declaration
  type-declaration
```

All kinds of class-member-declarations except finalizer-declaration are also struct-member-declarations. Except for the differences noted in §18.3, the descriptions of class members provided in §17.1.4 through §17.11 apply to struct members as well.

18.3 Class and struct differences

18.3.1 Value semantics
Structs are value types (§11.1) and are said to have value semantics. Classes, on the other hand, are reference types (§11.2) and are said to have reference semantics.

A variable of a struct type directly contains the data of the struct, whereas a variable of a class type contains a reference to the data, the latter known as an object.

With classes, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With structs, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other. Furthermore, because structs are not reference types, it is not possible for values of a struct type to be null.

[Example: Given the declaration]
```csharp
struct Point
{
    public int x, y;
    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
```

the code fragment
```
Point a = new Point(10, 10);
Point b = a;
a.x = 100;
System.Console.WriteLine(b.x);
```

outputs the value 10. The assignment of a to b creates a copy of the value, and b is thus unaffected by the assignment to a.x. Had Point instead been declared as a class, the output would be 100 because a and b would reference the same object. end example]

### 18.3.2 Inheritance

All struct types implicitly inherit from `System.ValueType`, which, in turn, inherits from class `object`. A struct declaration can specify a list of implemented interfaces, but it is not possible for a struct declaration to specify a base class.

Struct types are never abstract and are always implicitly sealed. The `abstract` and `sealed` modifiers are therefore not permitted in a struct declaration.

Since inheritance isn't supported for structs, the declared accessibility of a struct member cannot be `protected` or `protected internal`.

Function members in a struct cannot be `abstract` or `virtual`, and the `override` modifier is allowed only to override methods inherited from the type `System.ValueType`.

### 18.3.3 Assignment

Assignment to a variable of a struct type creates a copy of the value being assigned. This differs from assignment to a variable of a class type, which copies the reference but not the object identified by the reference.

Similar to an assignment, when a struct is passed as a value parameter or returned as the result of a function member, a copy of the struct is created. A struct can be passed by reference to a function member using a `ref` or `out` parameter.

When a property or indexer of a struct is the target of an assignment, the instance expression associated with the property or indexer access shall be classified as a variable. If the instance expression is classified as a value, a compile-time error occurs. This is described in further detail in §14.14.1.

### 18.3.4 Default values

As described in §12.2, several kinds of variables are automatically initialized to their default value when they are created. For variables of class types and other reference types, this default value is `null`. However, since structs are value types that cannot be `null`, the default value of a struct is the value produced by setting all value type fields to their default value and all reference type fields to `null`.

[Example: Referring to the `Point` struct declared above, the example
```
Point[] a = new Point[100];
```
initializes each `Point` in the array to the value produced by setting the `x` and `y` fields to zero. end example]

The default value of a struct corresponds to the value returned by the default constructor of the struct (§11.1.1). Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead,
every struct implicitly has a parameterless instance constructor, which always returns the value that results from setting all value type fields to their default value and all reference type fields to null.

[Note: Structs should be designed to consider the default initialization state a valid state. In the example

```csharp
using System;

struct KeyValuePair
{
    string key;
    string value;
    public KeyValuePair(string key, string value) {
        if (key == null || value == null) throw new ArgumentException();
        this.key = key;
        this.value = value;
    }
}
```

the user-defined instance constructor protects against null values only where it is explicitly called. In cases where a `KeyValuePair` variable is subject to default value initialization, the `key` and `value` fields will be null, and the struct should be prepared to handle this state. end note]

18.3.5 Boxing and unboxing

A value of a class type can be converted to type `object` or to an interface type that is implemented by the class simply by treating the reference as another type at compile-time. Likewise, a value of type `object` or a value of an interface type can be converted back to a class type without changing the reference (but, of course, a run-time type check is required in this case).

Since structs are not reference types, these operations are implemented differently for struct types. When a value of a struct type is converted to type `object` or to an interface type that is implemented by the struct, a boxing operation takes place. Likewise, when a value of type `object` or a value of an interface type is converted back to a struct type, an unboxing operation takes place. A key difference from the same operations on class types is that boxing and unboxing copies the struct value either into or out of the boxed instance. [Note: Thus, following a boxing or unboxing operation, changes made to the unboxed struct are not reflected in the boxed struct. end note]

For further details on boxing and unboxing, see §11.3.

18.3.6 Meaning of this

Within an instance constructor or instance function member of a class, `this` is classified as a value. Thus, while `this` can be used to refer to the instance for which the function member was invoked, it is not possible to assign to `this` in a function member of a class.

Within an instance constructor of a struct, `this` corresponds to an `out` parameter of the struct type, and within an instance function member of a struct, `this` corresponds to a `ref` parameter of the struct type. In both cases, `this` is classified as a variable, and it is possible to modify the entire struct for which the function member was invoked by assigning to `this` or by passing `this` as a `ref` or `out` parameter.

18.3.7 Field initializers

As described in §18.3.4, the default value of a struct consists of the value that results from setting all value type fields to their default value and all reference type fields to `null`. For this reason, a struct does not permit instance field declarations to include variable initializers. [Example: As such, the following example results in one or more compile-time errors:

```csharp
struct Point
{
    public int x = 1;  // Error, initializer not permitted
    public int y = 1;  // Error, initializer not permitted
}
```

end example]
This restriction applies only to instance fields. Static fields of a struct are permitted to include variable initializers.

### 18.3.8 Constructors

Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead, every struct implicitly has a parameterless instance constructor, which always returns the value that results from setting all value type fields to their default value and all reference type fields to \texttt{null} (§11.1.1). A struct can declare instance constructors having parameters. [Example:

```c
struct Point
{
    int x, y;
    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
```

Given the above declaration, the statements

```c
Point p1 = new Point();
Point p2 = new Point(0, 0);
```

both create a \texttt{Point} with \texttt{x} and \texttt{y} initialized to zero. \textit{end example}]

A struct instance constructor is not permitted to include a constructor initializer of the form \texttt{base(argument-listopt}).

The \texttt{this} variable of a struct instance constructor corresponds to an \texttt{out} parameter of the struct type, and similar to an \texttt{out} parameter, \texttt{this} shall be definitely assigned (§12.3) at every location where the constructor returns. [Example: Consider the instance constructor implementation below:

```c
struct Point
{
    int x, y;
    public int X {
        set { x = value; }
    }
    public int Y {
        set { y = value; }
    }
    public Point(int x, int y) {
        X = x;  // error, this is not yet definitely assigned
        Y = y;  // error, this is not yet definitely assigned
    }
}
```

No instance member function (including the set accessors for the properties \texttt{X} and \texttt{Y}) can be called until all fields of the struct being constructed have been definitely assigned. Note, however, that if \texttt{Point} were a class instead of a struct, the instance constructor implementation would be permitted. \textit{end example}]

### 18.3.9 Finalizers

A struct is not permitted to declare a finalizer.

### 18.3.10 Static constructors

Static constructors for structs follow most of the same rules as for classes. The execution of a static constructor for a struct is triggered by the first of the following events to occur within an application domain:

- An instance member of the struct is referenced.
• A static member of the struct is referenced.
• An explicitly declared constructor of the struct is called.

[Note: The creation of default values (§18.3.4) of struct types does not trigger the static constructor. (An example of this is the initial value of elements in an array.) end note]
19. Arrays

An array is a data structure that contains a number of variables that are accessed through computed indices. The variables contained in an array, also called the elements of the array, are all of the same type, and this type is called the element type of the array.

An array has a rank that determines the number of indices associated with each array element. The rank of an array is also referred to as the dimensions of the array. An array with a rank of one is called a single-dimensional array. An array with a rank greater than one is called a multi-dimensional array. Specific sized multi-dimensional arrays are often referred to as two-dimensional arrays, three-dimensional arrays, and so on. Each dimension of an array has an associated length that is an integral number greater than or equal to zero. The dimension lengths are not part of the type of the array, but rather are established when an instance of the array type is created at run-time. The length of a dimension determines the valid range of indices for that dimension: For a dimension of length N, indices can range from 0 to N – 1 inclusive. The total number of elements in an array is the product of the lengths of each dimension in the array. If one or more of the dimensions of an array have a length of zero, the array is said to be empty.

The element type of an array can be any type, including an array type.

19.1 Array types

An array type is written as a non-array-type followed by one or more rank-specifiers:

array-type:
  non-array-type  rank-specifiers

non-array-type:
  value-type
  class-type
  interface-type
  delegate-type
  type-parameter

rank-specifiers:
  rank-specifier
  rank-specifiers  rank-specifier

rank-specifier:
  [  dim-separators,  ]

dim-separators:
  ,
  dim-separators

A non-array-type is any type that is not itself an array-type.

The rank of an array type is given by the leftmost rank-specifier in the array-type: A rank-specifier indicates that the array is an array with a rank of one plus the number of “,” tokens in the rank-specifier.

The element type of an array type is the type that results from deleting the leftmost rank-specifier:

- An array type of the form T[R] is an array with rank R and a non-array element type T.
- An array type of the form T[R][R₁]…[Rₙ] is an array with rank R and an element type T[R₁]…[Rₙ].
In effect, the rank-specifiers are read from left to right before the final non-array element type. [Example: The type int[][][,,] is a single-dimensional array of three-dimensional arrays of two-dimensional arrays of int. end example]

At run-time, a value of an array type can be null or a reference to an instance of that array type or a covariant array type, as described in §19.5.

19.1.1 The System.Array type
The type System.Array is the abstract base type of all array types. An implicit reference conversion (§13.1.4) exists from any array type to System.Array and to any interface type implemented by System.Array. An explicit reference conversion (§13.2.3) exists from System.Array and any interface type implemented by System.Array to any array type. System.Array is not itself an array-type. Rather, it is a class-type from which all array-types are derived.

At run-time, a value of type System.Array can be null or a reference to an instance of any array type.

19.2 Array creation
Array instances are created explicitly by array-creation-expressions (§14.5.10.2) or by field or local variable declarations that include an array-initializer (§19.6). Array instances can also be created implicitly by invoking a method in its expanded form (§14.4.1).

When an array instance is created, the rank and length of each dimension are established and then remain constant for the entire lifetime of the instance. In other words, it is not possible to change the rank of an existing array instance, nor is it possible to resize its dimensions.

An array instance is always of an array type. The System.Array type is an abstract type that cannot be instantiated.

Elements of arrays created by array-creation-expressions are always initialized to their default value (§12.2).

19.3 Array element access
Array elements are accessed using element-access expressions (§14.5.6.1) of the form A[I1, I2, ..., In], where A is an expression of an array type and each IX is an expression of type int, uint, long, ulong, or of a type that can be implicitly converted to one or more of these types. The result of an array element access is a variable, namely the array element selected by the indices.

The elements of an array can be enumerated using a foreach statement (§15.8.4).

19.4 Array members
Every array type inherits the members declared by the System.Array type.

19.5 Array covariance
For any two reference-types A and B, if an implicit reference conversion (§13.1.4) or explicit reference conversion (§13.2.3) exists from A to B, then the same reference conversion also exists from the array type A[R] to the array type B[R], where R is any given rank-specifier (but the same for both array types). This relationship is known as array covariance. Array covariance, in particular, means that a value of an array type A[R] might actually be a reference to an instance of an array type B[R], provided an implicit reference conversion exists from B to A.

Because of array covariance, assignments to elements of reference type arrays include a run-time check which ensures that the value being assigned to the array element is actually of a permitted type (§14.14.1). [Example:
class Test
{
    static void Fill(object[] array, int index, int count, object value) {
        for (int i = index; i < index + count; i++) array[i] = value;
    }
    static void Main() {
        string[] strings = new string[100];
        Fill(strings, 0, 100, "Undefined");
        Fill(strings, 0, 10, null);
        Fill(strings, 90, 10, 0);
    }
}

The assignment to array[i] in the Fill method implicitly includes a run-time check, which ensures that the object referenced by value is either null or an instance of a type that is compatible with the actual element type of array. In Main, the first two invocations of Fill succeed, but the third invocation causes a System.ArrayTypeMismatchException to be thrown upon executing the first assignment to array[i]. The exception occurs because a boxed int cannot be stored in a string array. end example

Array covariance specifically does not extend to arrays of value-types. For example, no conversion exists that permits an int[] to be treated as an object[].

19.6 Arrays and the generic IList interface

A one-dimensional array S[] implements the interface System.Collections.Generic.IList<S> (IList<S> for short) and its base interfaces. Accordingly, there is an implicit conversion from S[] to IList<S> and its base interfaces. In addition, if there is an implicit reference conversion from S to T then S[] implements IList<T> and there is an implicit reference conversion from S[] to IList<T> and its base interfaces (§13.1.4). If there is an explicit reference conversion from S to T then there is an explicit reference conversion from S[] to IList<T> and its base interfaces (§13.2.3). [Example: For example:

using System.Collections.Generic;
class Test
{
    static void Main() {
        string[] sa = new string[5];
        object[] oa1 = new object[5];
        object[] oa2 = sa;
        IList<string> lst1 = sa; // OK
        IList<string> lst2 = oa1; // Error - need cast
        IList<object> lst3 = sa; // OK
        IList<object> lst4 = oa1; // OK
        IList<string> lst5 = (IList<string>)oa1; // Exception
        IList<string> lst6 = (IList<string>)oa2; // OK
    }
}

The assignment lst2 = oa1 generates a compile-time error since the conversion from object[] to IList<string> is an explicit conversion, not implicit. The cast (IList<string>)oa1 will cause an exception to be thrown at runtime since oa1 references an object[] and not a string[]. However the cast (IList<string>)oa2 will not cause an exception to be thrown since oa2 references a string[]. end example]

Whenever there is an implicit or explicit reference conversion from S[] to IList<T>, there is also an explicit reference conversion from IList<T> and its base interfaces to S[] (§13.2.3).

When an array type S[] implements IList<T>, some of the members of the implemented interface may throw exceptions. The precise behavior of the implementation of the interface is beyond the scope of this specification.
19.7 Array initializers

Array initializers can be specified in field declarations (§17.4), local variable declarations (§15.5.1), and array creation expressions (§14.5.10.2):

array-initializer:
\[
\begin{align*}
&\{ \text{variable-initializer-listopt} \} \\
&\{ \text{variable-initializer-list} , \}
\end{align*}
\]

variable-initializer-list:
\[
\text{variable-initializer} \\
\text{variable-initializer-list} , \text{variable-initializer}
\]

variable-initializer:
\[
\text{expression} \\
\text{array-initializer}
\]

An array initializer consists of a sequence of variable initializers, enclosed by “{” and “}” tokens and separated by “,” tokens. Each variable initializer is an expression or, in the case of a multi-dimensional array, a nested array initializer.

The context in which an array initializer is used determines the type of the array being initialized. In an array creation expression, the array type immediately precedes the initializer. In a field or variable declaration, the array type is the type of the field or variable being declared. When an array initializer is used in a field or variable declaration, [Example:
\[
\text{int}[\text{]} \ a = \{0, 2, 4, 6, 8\};
\]
end example] it is simply shorthand for an equivalent array creation expression: [Example:
\[
\text{int}[\text{]} \ a = \text{new int}[\text{]} \ {0, 2, 4, 6, 8};
\]
end example]

For a single-dimensional array, the array initializer shall consist of a sequence of expressions that are assignment compatible with the element type of the array. The expressions initialize array elements in increasing order, starting with the element at index zero. The number of expressions in the array initializer determines the length of the array instance being created. [Example: The array initializer above creates an \text{int}[\text{]} instance of length 5 and then initializes the instance with the following values:
\[
\]
end example]

For a multi-dimensional array, the array initializer shall have as many levels of nesting as there are dimensions in the array. The outermost nesting level corresponds to the leftmost dimension and the innermost nesting level corresponds to the rightmost dimension. The length of each dimension of the array is determined by the number of elements at the corresponding nesting level in the array initializer. For each nested array initializer, the number of elements shall be the same as the other array initializers at the same level. [Example: The example:
\[
\text{int}[,] \ b = \{\{0, 1\}, \{2, 3\}, \{4, 5\}, \{6, 7\}, \{8, 9\}\};
\]
creates a two-dimensional array with a length of five for the leftmost dimension and a length of two for the rightmost dimension:
\[
\text{int}[,] \ b = \text{new int}[5, 2];
\]
and then initializes the array instance with the following values:
\[
b[0, 0] = 0; b[0, 1] = 1; \\
b[1, 0] = 2; b[1, 1] = 3; \\
b[2, 0] = 4; b[2, 1] = 5; \\
b[3, 0] = 6; b[3, 1] = 7; \\
b[4, 0] = 8; b[4, 1] = 9;
\]
end example]
When an array creation expression includes both explicit dimension lengths and an array initializer, the lengths shall be constant expressions and the number of elements at each nesting level shall match the corresponding dimension length. [Example: Here are some examples:

```c
int i = 3;
int[] x = new int[3] {0, 1, 2};  // OK
int[] y = new int[i] {0, 1, 2};  // Error, i not a constant
int[] z = new int[3] {0, 1, 2, 3}; // Error, length/initializer mismatch
```

Here, the initializer for `y` results in a compile-time error because the dimension length expression is not a constant, and the initializer for `z` results in a compile-time error because the length and the number of elements in the initializer do not agree. end example]

[Note: Like Standard C++, C# allows a trailing comma at the end of an array-initializer. This syntax provides flexibility in adding or deleting members from such a list, and simplifies machine generation of such lists. end note]
20. Interfaces

An interface defines a contract. A class or struct that implements an interface shall adhere to its contract. An interface can inherit from multiple base interfaces, and a class or struct can implement multiple interfaces.

Interfaces can contain methods, properties, events, and indexers. The interface itself does not provide implementations for the members that it declares. The interface merely specifies the members that shall be supplied by classes or interfaces that implement the interface.

20.1 Interface declarations

An interface-declaration is a type-declaration (§16.6) that declares a new interface type.

interface-declaration:
   attributesopt interface-modifiersopt partialopt interface identifier type-parameter-listopt
   interface-baseopt type-parameter-constraints-clausesopt interface-body ;opt

An interface-declaration consists of an optional set of attributes (§24), followed by an optional set of interface-modifiers (§20.1.1), followed by an optional partial modifier (§17.1.4), followed by the keyword interface and an identifier that names the interface, followed by an optional type-parameter-list (§25.1.1), followed by an optional interface-base specification (§20.1.2), followed by an optional type-parameter-constraints-clauses (§25.7), followed by an interface-body (§20.1.3), optionally followed by a semicolon.

An interface declaration shall not supply a type-parameter-constraints-clauses unless it also supplies a type-parameter-list.

An interface declaration that supplies a type-parameter-list is a generic interface declaration (§25.3).

20.1.1 Interface modifiers

An interface-declaration can optionally include a sequence of interface modifiers:

interface-modifiers:
   interface-modifier
   interface-modifiers interface-modifier

interface-modifier:
   new
   public
   protected
   internal
   private

It is a compile-time error for the same modifier to appear multiple times in an interface declaration.

The new modifier is only permitted on nested interfaces. It specifies that the interface hides an inherited member by the same name, as described in §17.2.2.

The public, protected, internal, and private modifiers control the accessibility of the interface. Depending on the context in which the interface declaration occurs, only some of these modifiers might be permitted (§10.5.1). When a partial type declaration (§17.1.4) includes an accessibility specification (via the public, protected, internal, and private modifiers), the rules in §17.1.1 apply.
20.1.2 Base interfaces
An interface can inherit from one or more interfaces, which are called the explicit base interfaces of the interface. When an interface has one or more explicit base interfaces, then in the declaration of that interface, the interface identifier is followed by a colon and a comma-separated list of base interfaces.

```
interface-base:
  : interface-type-list
```

The explicit base interfaces can be constructed interface types (§25.5). A base interface cannot be a type parameter on its own, though it can involve the type parameters that are in scope.

The explicit base interfaces (and any type arguments) of an interface shall be at least as accessible as the interface itself (§10.5.4). [Note: For example, it is a compile-time error to specify a private or internal interface in the interface-base of a public interface. end note]

It is a compile-time error for an interface to directly or indirectly inherit from itself.

The base interfaces of an interface are the explicit base interfaces and their base interfaces (after substituting type arguments for type parameters in constructed generic types). In other words, the set of base interfaces is the complete transitive closure of the explicit base interfaces, their explicit base interfaces, and so on. An interface inherits all members of its base interfaces. [Example: In the following code]

```
interface IControl
{ void Paint(); }

interface ITextBox: IControl
{ void SetText(string text); }

interface IListBox: IControl
{ void SetItems(string[] items); }

interface IComboBox: ITextBox, IListBox {}
```

the base interfaces of IComboBox are IControl, ITextBox, and IListBox. In other words, the IComboBox interface above inherits members SetText and SetItems as well as Paint. [end example]

Members inherited from a constructed generic type are inherited after type substitution. That is, any constituent types in the member have the base class declaration’s type parameters replaced with the corresponding type arguments used in the class-base specification. [Example: In the following code]

```
interface IBase<T>
{ T[] Combine(T a, T b); }

interface IDerived : IBase<string[,]>
{ // Inherited: string[,][,] Combine(string[,,] a, string[,] b); }
```

the interface IDerived inherits the Combine method after the type parameter T is replaced with string[,,]. [end example]

A class or struct that implements an interface also implicitly implements all of the interface’s base interfaces.

The handling of interfaces on multiple parts of a partial interface declaration (§17.1.4) are discussed further in §17.1.2.2.

20.1.3 Interface body
The interface-body of an interface defines the members of the interface.
interface-body:
    { interface-member-declarations_opt }

20.2 Interface members

The members of an interface are the members inherited from the base interfaces and the members declared by the interface itself.

interface-member-declarations:
    interface-member-declaration
    interface-member-declarations   interface-member-declaration

interface-member-declaration:
    interface-method-declaration
    interface-property-declaration
    interface-event-declaration
    interface-indexer-declaration

An interface declaration can declare zero or more members. The members of an interface shall be methods, properties, events, or indexers. An interface cannot contain constants, fields, operators, instance constructors, finalizers, or types, nor can an interface contain static members of any kind.

All interface members implicitly have public access. It is a compile-time error for interface member declarations to include any modifiers. In particular, interface members cannot be declared with the modifiers abstract, public, protected, internal, private, virtual, override, or static.

[Example: The example]

    public delegate void StringListEventHandler(IStringList sender, ListEventArgs e);
    public interface IStringList
    { void Add(string s);
      int Count { get; }
      event StringListEventHandler Changed;
      string this[int index] { get; set; }
    }

declares an interface that contains one each of the possible kinds of members: A method, a property, an event, and an indexer. end example]

An interface-declaration creates a new declaration space (§10.3), and the type parameters and interface-member-declarations immediately contained by the interface-declaration introduce new members into this declaration space. The following rules apply to interface-member-declarations:

• The name of a type parameter in the type-parameter-list of an interface declaration shall differ from the names of all other type parameters in the same type-parameter-list and shall differ from the names of all members of the interface.

• The name of a method shall differ from the names of all properties and events declared in the same interface. In addition, the signature (§10.6) of a method shall differ from the signatures of all other methods declared in the same interface, and two methods declared in the same interface shall not have signatures that differ solely by ref and out.

• The name of a property or event shall differ from the names of all other members declared in the same interface.

• The signature of an indexer shall differ from the signatures of all other indexers declared in the same interface.

The inherited members of an interface are specifically not part of the declaration space of the interface. Thus, an interface is allowed to declare a member with the same name or signature as an inherited member.
When this occurs, the derived interface member is said to *hide* the base interface member. Hiding an inherited member is not considered an error, but it does cause the compiler to issue a warning. To suppress the warning, the declaration of the derived interface member shall include a `new` modifier to indicate that the derived member is intended to hide the base member. This topic is discussed further in §10.7.1.2.

If a `new` modifier is included in a declaration that doesn’t hide an inherited member, a warning is issued to that effect. This warning is suppressed by removing the `new` modifier.

*[Note: The members in class `object` are not, strictly speaking, members of any interface (§20.2). However, the members in class `object` are available via member lookup in any interface type (§14.3). end note]*

For a discussion about members of an interface declared in multiple parts (§17.1.4), see §17.2.

### 20.2.1 Interface methods

Interface methods are declared using `interface-method-declarations`:

```
interface-method-declaration:
  attributes opt  new opt  return-type  identifier  type-parameter-list opt
  (  formal-parameter-list opt  )  type-parameter-constraints-clauses opt  ;
```

The `attributes`, `return-type`, `identifier`, and `formal-parameter-list` of an interface method declaration have the same meaning as those of a method declaration in a class (§17.5). An interface method declaration is not permitted to specify a method body; therefore, the declaration always ends with a semicolon. An `interface-method-declaration` shall not have `type-parameter-constraints-clauses` unless it also has a `type-parameter-list`.

### 20.2.2 Interface properties

Interface properties are declared using `interface-property-declarations`:

```
interface-property-declaration:
  attributes opt  new opt  type  identifier  {  interface-accessors  }
```

```
interface-accessors:
  attributes opt  get  ;
  attributes opt  set  ;
  attributes opt  get ;  attributes opt  set ;
  attributes opt  set ;  attributes opt  get ;
```

The `attributes`, `type`, and `identifier` of an interface property declaration have the same meaning as those of a property declaration in a class (§17.6).

The accessors of an interface property declaration correspond to the accessors of a class property declaration (§17.6.2), except that the accessor body shall always be a semicolon. Thus, the accessors simply indicate whether the property is read-write, read-only, or write-only.

### 20.2.3 Interface events

Interface events are declared using `interface-event-declarations`:

```
interface-event-declaration:
  attributes opt  new opt  event  type  identifier  ;
```

The `attributes`, `type`, and `identifier` of an interface event declaration have the same meaning as those of an event declaration in a class (§17.7).

### 20.2.4 Interface indexers

Interface indexers are declared using `interface-indexer-declarations`:

```
interface-indexer-declaration:
  attributes opt  new opt  type  this  [  formal-parameter-list  ]  {  interface-accessors  }
```
The attributes, type, and formal-parameter-list of an interface indexer declaration have the same meaning as those of an indexer declaration in a class (§17.8).

The accessors of an interface indexer declaration correspond to the accessors of a class indexer declaration (§17.8), except that the accessor body shall always be a semicolon. Thus, the accessors simply indicate whether the indexer is read-write, read-only, or write-only.

20.2.5 Interface member access

Interface members are accessed through member access (§14.5.4) and indexer access (§14.5.6.2) expressions of the form I.M and I[A], where I is an expression having an interface type, M is a method, property, or event of that interface type, and A is an indexer argument list.

For interfaces that are strictly single-inheritance (each interface in the inheritance chain has exactly zero or one direct base interface), the effects of the member lookup (§14.3), method invocation (§14.5.5.1), and indexer access (§14.5.6.2) rules are same as for classes and structs: More derived members hide less derived members with the same name or signature. However, for multiple-inheritance interfaces, ambiguities can occur when two or more unrelated base interfaces declare members with the same name or signature. This subclause shows several examples of such situations. In all cases, explicit casts can be used to resolve the ambiguities.

Example: In the following code

```csharp
interface IList
{
    int Count { get; set; }
}

interface ICounter
{
    void Count(int i);
}

interface IListCounter: IList, ICounter {}

class C
{
    void Test(IListCounter x)
    {
        x.Count(1);   // Error
        x.Count = 1;   // Error
        ((IList)x).Count = 1; // Ok, invokes IList.Count.set
        ((ICounter)x).Count(1); // Ok, invokes ICounter.Count
    }
}
```

the first two statements cause compile-time errors because the member lookup (§14.3) of Count in IListCounter is ambiguous. As illustrated by the example, the ambiguity is resolved by casting x to the appropriate base interface type. Such casts have no run-time costs—they merely consist of viewing the instance as a less derived type at compile-time. end example

Example: In the following code

```csharp
interface IInteger
{
    void Add(int i);
}

interface IDouble
{
    void Add(double d);
}

interface INumber: IInteger, IDouble {}
```
class C
{
    void Test(INumber n) {
        n.Add(1);     // Error, both Add methods are applicable
        n.Add(1.0);     // Ok, only IDouble.Add is applicable
        ((IInteger)n).Add(1); // Ok, only IInteger.Add is a candidate
        ((IDouble)n).Add(1);  // Ok, only IDouble.Add is a candidate
    }
}

the invocation \(n.Add(1)\) is ambiguous because a method invocation (§14.5.5.1) requires all overloaded candidate methods to be declared in the same type. However, the invocation \(n.Add(1.0)\) is permitted because only IDouble.Add is applicable. When explicit casts are inserted, there is only one candidate method, and thus no ambiguity. *end example*

[Example: In the following code

```csharp
interface IBase
{
    void F(int i);
}

interface ILeft: IBase
{
    new void F(int i);
}

interface IRight: IBase
{
    void G();
}

interface IDerived: ILeft, IRight {}

class A
{
    void Test(IDerived d) {
        d.F(1);     // Invokes ILeft.F
        ((IBase)d).F(1);  // Invokes IBase.F
        ((ILeft)d).F(1);  // Invokes ILeft.F
        ((IRight)d).F(1);  // Invokes IBase.F
    }
}
```

the IBase.F member is hidden by the ILeft.F member. The invocation \(d.F(1)\) thus selects ILeft.F, even though IBase.F appears to not be hidden in the access path that leads through IRight.

The intuitive rule for hiding in multiple-inheritance interfaces is simply this: If a member is hidden in any access path, it is hidden in all access paths. Because the access path from IDerived to ILeft to IBase hides IBase.F, the member is also hidden in the access path from IDerived to IRight to IBase. *end example*]

### 20.3 Fully qualified interface member names

An interface member is sometimes referred to by a *qualified interface member name*. A qualified interface member name consists of a name identifying the interface in which the member is declared, followed by a dot, followed by the name of the member. [*Example: Given the declarations*

```csharp
interface IControl
{
    void Paint();
}

interface ITextBox: IControl
{
    void SetText(string text);
}
```

```csharp
interface IBase
{
    void F(int i);
}
```
a qualified interface member name for Paint is IControl.Paint and a qualified interface member name for SetText is ITextBox.SetText. In the example above, it is not possible to refer to Paint as ITextBox.Paint. end example]

When an interface is part of a namespace, a qualified interface member name can include the namespace name. [Example:

```csharp
namespace System
{
    public interface ICloneable
    {
        object Clone();
    }
}
```

Within the System namespace, both ICloneable.Clone and System.ICloneable.Clone are qualified interface member names for the Clone method. end example]

### 20.4 Interface implementations

Interfaces can be implemented by classes and structs. To indicate that a class or struct implements an interface, the interface is included in the base class list of the class or struct. [Example:

```csharp
interface ICloneable
{
    object Clone();
}
interface IComparable
{
    int CompareTo(object other);
}
class ListEntry: ICloneable, IComparable
{
    public object Clone() {...}
    public int CompareTo(object other) {...}
}
```

end example]

A class or struct that implements an interface also implicitly implements all of the interface’s base interfaces. This is true even if the class or struct doesn’t explicitly list all base interfaces in the base class list. [Example:

```csharp
interface IControl
{
    void Paint();
}
interface ITextBox: IControl
{
    void SetText(string text);
}
class TextBox: ITextBox
{
    public void Paint() {...}
    public void SetText(string text) {...}
}
```

Here, class TextBox implements both IControl and ITextBox. end example]

### 20.4.1 Explicit interface member implementations

For purposes of implementing interfaces, a class or struct can declare **explicit interface member implementations**. An explicit interface member implementation is a method, property, event, or indexer declaration that references a qualified interface member name. [Example:
interface ICloneable
{
    object Clone();
}

interface IComparable
{
    int CompareTo(object other);
}

class ListEntry: ICloneable, IComparable
{
    object ICloneable.Clone() {...}
    int IComparable.CompareTo(object other) {...}
}

Here, ICloneable.Clone and IComparable.CompareTo are explicit interface member implementations.

[Example: In some cases, the name of an interface member might not be appropriate for the implementing class, in which case, the interface member can be implemented using explicit interface member implementation. A class implementing a file abstraction, for example, would likely implement a Close member function that has the effect of releasing the file resource, and implement the Dispose method of the IDisposable interface using explicit interface member implementation:

    interface IDisposable
    {
        void Dispose();
    }
    class MyFile: IDisposable
    {
        void IDisposable.Dispose()
        {
            Close();
        }
        public void Close()
        {
            // Do what's necessary to close the file
            System.GC.SuppressFinalize(this);
        }
    }

end example]

It is not possible to access an explicit interface member implementation through a qualified interface member name in a method invocation, property access, event access, or indexer access. An explicit interface member implementation can only be accessed through an interface instance, and is in that case referenced simply by its member name.

It is a compile-time error for an explicit interface member implementation to include any modifiers other than extern (§17.5). It is a compile-time error for an explicit interface method implementation to include type-parameter-constraints-clauses. The constraints for a generic explicit interface method implementation are inherited from the interface method.

Explicit interface member implementations have different accessibility characteristics than other members. Because explicit interface member implementations are never accessible through a qualified interface member name in a method invocation or a property access, they are in a sense private. However, since they can be accessed through an interface instance, they are in a sense also public.

Explicit interface member implementations serve two primary purposes:

- Because explicit interface member implementations are not accessible through class or struct instances, they allow interface implementations to be excluded from the public interface of a class or struct. This is particularly useful when a class or struct implements an internal interface that is of no interest to a consumer of that class or struct.
• Explicit interface member implementations allow disambiguation of interface members with the same signature. Without explicit interface member implementations it would be impossible for a class or struct to have different implementations of interface members with the same signature and return type, as would it be impossible for a class or struct to have any implementation at all of interface members with the same signature but with different return types.

For an explicit interface member implementation to be valid, the class or struct shall name an interface in its base class list that contains a member whose containing type, name, type, number of type parameters, and parameter types exactly match those of the explicit interface member implementation. If an interface function member has a parameter array, the corresponding parameter of an associated explicit interface member implementation is allowed, but not required, to have the `params` modifier. If the interface function member does not have a parameter array then an associated explicit interface member implementation shall not have a parameter array. [Example: Thus, in the following class

```csharp
class Shape: ICloneable
{
    object ICloneable.Clone() {...}
    int IComparable.CompareTo(object other) {...} // invalid
}
```

the declaration of `ICloneable.CompareTo` results in a compile-time error because `ICloneable` is not listed in the base class list of `Shape` and is not a base interface of `ICloneable`. Likewise, in the declarations

```csharp
class Shape: ICloneable
{
    object ICloneable.Clone() {...}
}
class Ellipse: Shape
{
    object ICloneable.Clone() {...} // invalid
}
```

the declaration of `ICloneable.Clone` in `Ellipse` results in a compile-time error because `ICloneable` is not explicitly listed in the base class list of `Ellipse`. end example]

The qualified interface member name of explicit interface member implementation shall reference the interface in which the member was declared. [Example: Thus, in the declarations

```csharp
interface IControl
{
    void Paint();
}
interface ITextBox: IControl
{
    void SetText(string text);
}
class TextBox: ITextBox
{
    void IControl.Paint() {...}
    void ITextBox.SetText(string text) {...}
}
```

the explicit interface member implementation of `Paint` shall be written as `IControl.Paint` and not as `ITextBox.Paint`. end example]

### 20.4.2 Interface mapping

A class or struct shall provide implementations of all members of the interfaces that are listed in the base class list of the class or struct. The process of locating implementations of interface members in an implementing class or struct is known as *interface mapping*. 
Interface mapping for a class or struct $C$ locates an implementation for each member of each interface specified in the base class list of $C$. The implementation of a particular interface member $I.M$, where $I$ is the interface in which the member $M$ is declared, is determined by examining each class or struct $S$, starting with $C$ and repeating for each successive base class of $C$, until a match is located:

- If $S$ contains a declaration of an explicit interface member implementation that matches $I$ and $M$, then this member is the implementation of $I.M$.
- Otherwise, if $S$ contains a declaration of a non-static public member that matches $M$, then this member is the implementation of $I.M$.

A compile-time error occurs if implementations cannot be located for all members of all interfaces specified in the base class list of $C$. The members of an interface include those members that are inherited from base interfaces.

Members of a constructed interface type are considered to have any type parameters replaced with the corresponding type arguments as specified in §25.5.4. [Example: For example, given the generic interface declaration:

```csharp
interface I<T>
{
    T F(int x, T[,] y);
    T this[int y] { get; }
}
```

the constructed interface $I<string[]>$ has the members:

```csharp
string[,] F(int x, string[,] y);
string[,] this[int y] { get; }
```

end example]

For purposes of interface mapping, a class member $A$ matches an interface member $B$ when:

- $A$ and $B$ are methods, and the name, type, and formal parameter lists of $A$ and $B$ are identical.
- $A$ and $B$ are properties, the name and type of $A$ and $B$ are identical, and $A$ has the same accessors as $B$ ($A$ is permitted to have additional accessors if it is not an explicit interface member implementation).
- $A$ and $B$ are events, and the name and type of $A$ and $B$ are identical.
- $A$ and $B$ are indexers, the type and formal parameter lists of $A$ and $B$ are identical, and $A$ has the same accessors as $B$ ($A$ is permitted to have additional accessors if it is not an explicit interface member implementation).

Notable implications of the interface-mapping algorithm are:

- Explicit interface member implementations take precedence over other members in the same class or struct when determining the class or struct member that implements an interface member.
- Neither non-public nor static members participate in interface mapping.

[Example: In the following code

```csharp
interface ICloneable
{
    object Clone();
}

class C: ICloneable
{
    object ICloneable.Clone() {...}
    public object Clone() {...}
}
```

the $ICloneable.Clone$ member of $C$ becomes the implementation of $Clone$ in $ICloneable$ because explicit interface member implementations take precedence over other members. end example]
If a class or struct implements two or more interfaces containing a member with the same name, type, and parameter types, it is possible to map each of those interface members onto a single class or struct member. 

**Example:**

```csharp
interface IControl
{
    void Paint();
}
interface IForm
{
    void Paint();
}
class Page: IControl, IForm
{
    public void Paint() {...}
}
```

Here, the `Paint` methods of both `IControl` and `IForm` are mapped onto the `Paint` method in `Page`. It is of course also possible to have separate explicit interface member implementations for the two methods. *end example*

If a class or struct implements an interface that contains hidden members, then some members shall necessarily be implemented through explicit interface member implementations. **Example:**

```csharp
interface IBase
{
    int P { get; }
}
interface IDerived: IBase
{
    new int P();
}
```

An implementation of this interface would require at least one explicit interface member implementation, and would take one of the following forms

```csharp
class C: IDerived
{
    int IBase.P { get {...} }  
    int IDerived.P() {...}
}
class C: IDerived
{
    public int P { get {...} }  
    int IDerived.P() {...}
}
class C: IDerived
{
    int IBase.P { get {...} }  
    public int P() {...}
}
```

*end example*

When a class implements multiple interfaces that have the same base interface, there can be only one implementation of the base interface. **Example:** In the following code

```csharp
interface IControl
{
    void Paint();
}
```
interface ITextBox: IControl
{
  void SetText(string text);
}

interface IListBox: IControl
{
  void SetItems(string[] items);
}

class ComboBox: IControl, ITextBox, IListBox
{
  void IControl.Paint() {…}
  void ITextBox.SetText(string text) {…}
  void IListBox.SetItems(string[] items) {…}
}
it is not possible to have separate implementations for the IControl named in the base class list, the
IControl inherited by ITextBox, and the IControl inherited by IListBox. Indeed, there is no notion of
a separate identity for these interfaces. Rather, the implementations of ITextBox and IListBox share
the same implementation of IControl, and ComboBox is simply considered to implement three interfaces,
IControl, ITextBox, and IListBox. [end example]

The members of a base class participate in interface mapping. [Example: In the following code

interface Interface1
{
  void F();
}

class Class1
{
  public void F() {}
  public void G() {}
}

class Class2: Class1, Interface1
{
  new public void G() {}
}

the method F in Class1 is used in Class2’s implementation of Interface1. [end example]

20.4.3 Interface implementation inheritance

A class inherits all interface implementations provided by its base classes.

Without explicitly re-implementing an interface, a derived class cannot alter the interface mappings it
inherits from its base classes. [Example: In the declarations

interface IControl
{
  void Paint();
}

class Control: IControl
{
  public void Paint() {…}
}

class TextBox: Control
{
  new public void Paint() {…}
}

the Paint method in TextBox hides the Paint method in Control, but it does not alter the mapping of
Control.Paint onto IControl.Paint, and calls to Paint through class instances and interface
instances will have the following effects
Control c = new Control();
TextBox t = new TextBox();
IControl ic = c;
IControl it = t;
c.Paint();   // invokes Control.Paint();
t.Paint();   // invokes TextBox.Paint();
ic.Paint();   // invokes Control.Paint();
it.Paint();   // invokes Control.Paint();

end example]

However, when an interface method is mapped onto a virtual method in a class, it is possible for derived classes to override the virtual method and alter the implementation of the interface. [Example: Rewriting the declarations above to

interface IControl
{  
  void Paint();
}
class Control: IControl
{  
  public virtual void Paint() {...}

class TextBox: Control
{  
  public override void Paint() {...}
}

the following effects will now be observed

Control c = new Control();
TextBox t = new TextBox();
IControl ic = c;
IControl it = t;
c.Paint();   // invokes Control.Paint();
t.Paint();   // invokes TextBox.Paint();
ic.Paint();   // invokes Control.Paint();
it.Paint();   // invokes TextBox.Paint();

end example]

Since explicit interface member implementations cannot be declared virtual, it is not possible to override an explicit interface member implementation. However, it is perfectly valid for an explicit interface member implementation to call another method, and that other method can be declared virtual to allow derived classes to override it. [Example:

interface IControl
{  
  void Paint();
}
class Control: IControl
{  
  void IControl.Paint() { PaintControl(); }  
  protected virtual void PaintControl() {...}
}
class TextBox: Control
{  
  protected override void PaintControl() {...}
}

Here, classes derived from Control can specialize the implementation of IControl.Paint by overriding the PaintControl method. end example]
20.4.4 Interface re-implementation

A class that inherits an interface implementation is permitted to re-implement the interface by including it in the base class list.

A re-implementation of an interface follows exactly the same interface mapping rules as an initial implementation of an interface. Thus, the inherited interface mapping has no effect whatsoever on the interface mapping established for the re-implementation of the interface. [Example: In the declarations

```csharp
interface IControl
{
    void Paint();
}
class Control: IControl
{
    void IControl.Paint() {...}
}
class MyControl: Control, IControl
{
    public void Paint() {}
}
```

the fact that `Control` maps `IControl.Paint` onto `Control.IControl.Paint` doesn’t affect the re-implementation in `MyControl`, which maps `IControl.Paint` onto `MyControl.Paint`. end example]

Inherited public member declarations and inherited explicit interface member declarations participate in the interface mapping process for re-implemented interfaces. [Example:

```csharp
interface IMetods
{
    void F();
    void G();
    void H();
    void I();
}
class Base: IMetods
{
    void IMetods.F() {}
    void IMetods.G() {}
    public void H() {}
    public void I() {}
}
class Derived: Base, IMetods
{
    public void F() {}
    void IMetods.H() {}
}
```

Here, the implementation of `IMetods` in `Derived` maps the interface methods onto `Derived.F`, `Base.IMetods.G`, `Derived.IMetods.H`, and `Base.I`. end example]

When a class implements an interface, it implicitly also implements all that interface’s base interfaces. Likewise, a re-implementation of an interface is also implicitly a re-implementation of all of the interface’s base interfaces. [Example:

```csharp
interface IBase
{
    void F();
}
interface IDerived: IBase
{
    void G();
}
class C: IDerived
{
    void IBase.F() {...}
}
Here, the re-implementation of IDerived also re-implements IBase, mapping IBase.F onto D.F.

20.4.5 Abstract classes and interfaces

Like a non-abstract class, an abstract class shall provide implementations of all members of the interfaces that are listed in the base class list of the class. However, an abstract class is permitted to map interface methods onto abstract methods. [Example:

```csharp
interface IMethods
{
    void F();
    void G();
}

abstract class C: IMethods
{
    public abstract void F();
    public abstract void G();
}
```

Here, the implementation of IMethods maps F and G onto abstract methods, which shall be overridden in non-abstract classes that derive from C. end example]

Explicit interface member implementations cannot be abstract, but explicit interface member implementations are of course permitted to call abstract methods. [Example:

```csharp
interface IMethods
{
    void F();
    void G();
}

abstract class C: IMethods
{
    void IMethods.F() { FF(); }
    void IMethods.G() { GG(); }
    protected abstract void FF();
    protected abstract void GG();
}
```

Here, non-abstract classes that derive from C would be required to override FF and GG, thus providing the actual implementation of IMethods. end example]
21. Enums

An enum type is a distinct type that declares a set of named constants. [Example: The example

```csharp
enum Color
{
    Red,
    Green,
    Blue
}
```
declares an enum type named Color with members Red, Green, and Blue. end example]

21.1 Enum declarations

An enum declaration declares a new enum type. An enum declaration begins with the keyword enum, and defines the name, accessibility, underlying type, and members of the enum.

```
enum-declaration:
    attributesopt enum-modifiersopt enum identifier enum-baseopt enum-body ;opt
enum-base:
    : integral-type
enum-body:
    { enum-member-declarationsopt }
    { enum-member-declarations , }
```

Each enum type has a corresponding integral type called the underlying type of the enum type. This underlying type shall be able to represent all the enumerator values defined in the enumeration. An enum declaration can explicitly declare an underlying type of byte, sbyte, short, ushort, int, uint, long or ulong. [Note: char cannot be used as an underlying type. end note] An enum declaration that does not explicitly declare an underlying type has an underlying type of int.

[Example: The example

```csharp
enum Color: long
{
    Red,
    Green,
    Blue
}
```
declares an enum with an underlying type of long. end example] [Note: A developer might choose to use an underlying type of long, as in the example, to enable the use of values that are in the range of long but not in the range of int, or to preserve this option for the future. end note]

[Note: C# allows a trailing comma in an enum-body, just like it allows one in an array-initializer (§19.6). end note]

21.2 Enum modifiers

An enum-declaration can optionally include a sequence of enum modifiers:

```
enum-modifiers:
    enum-modifier
    enum-modifiers enum-modifier
```
enum-modifier:
    new
    public
    protected
    internal
    private

It is a compile-time error for the same modifier to appear multiple times in an enum declaration.

The modifiers of an enum declaration have the same meaning as those of a class declaration (§17.1.1).
However, the abstract and sealed modifiers are not permitted in an enum declaration. Enums cannot be
abstract and do not permit derivation.

21.3 Enum members
The body of an enum type declaration defines zero or more enum members, which are the named constants
of the enum type. No two enum members can have the same name.

elem-member-declarations:
elem-member-declaration
elem-member-declarations , elem-member-declaration

elem-member-declaration:
    attributesopt identifier
    attributesopt identifier = constant-expression

Each enum member has an associated constant value. The type of this value is the underlying type for the
containing enum. The constant value for each enum member shall be in the range of the underlying type for
the enum. [Example: The example

enum Color: uint
{
    Red = -1,
    Green = -2,
    Blue = -3
}
results in a compile-time error because the constant values -1, -2, and -3 are not in the range of the
underlying integral type uint. end example]

Multiple enum members can share the same associated value. [Example: The example

elem Color
{
    Red,
    Green,
    Blue,

    Max = Blue
}
shows an enum that has two enum members—Blue and Max—that have the same associated value. end
example]

The associated value of an enum member is assigned either implicitly or explicitly. If the declaration of the
enum member has a constant-expression initializer, the value of that constant expression, implicitly
converted to the underlying type of the enum, is the associated value of the enum member. If the declaration
of the enum member has no initializer, its associated value is set implicitly, as follows:

• If the enum member is the first enum member declared in the enum type, its associated value is zero.

• Otherwise, the associated value of the enum member is obtained by increasing the associated value of
  the textually preceding enum member by one. This increased value shall be within the range of values
  that can be represented by the underlying type.
Example: The example

```csharp
using System;
enum Color
{
    Red,
    Green = 10,
    Blue
}
class Test
{
    static void Main()
    {
        Console.WriteLine(StringFromColor(Color.Red));
        Console.WriteLine(StringFromColor(Color.Green));
        Console.WriteLine(StringFromColor(Color.Blue));
    }
    static string StringFromColor(Color c)
    {
        switch (c)
        {
        case Color.Red:
            return String.Format("Red = {0}", (int) c);
        case Color.Green:
            return String.Format("Green = {0}", (int) c);
        case Color.Blue:
            return String.Format("Blue = {0}", (int) c);
        default:
            return "Invalid color";
        }
    }
}
```

prints out the enum member names and their associated values. The output is:

```
Red = 0
Green = 10
Blue = 11
```

for the following reasons:

- the enum member `Red` is automatically assigned the value zero (since it has no initializer and is the first enum member);
- the enum member `Green` is explicitly given the value 10;
- and the enum member `Blue` is automatically assigned the value one greater than the member that textually precedes it.

end example

The associated value of an enum member shall not, directly or indirectly, use the value of its own associated enum member. Other than this circularity restriction, enum member initializers can freely refer to other enum member initializers, regardless of their textual position. Within an enum member initializer, values of other enum members are always treated as having the type of their underlying type, so that casts are not necessary when referring to other enum members.

Example: The example

```
enum Circular
{
    A = B,
    B
}
```

results in a compile-time error because the declarations of `A` and `B` are circular. `A` depends on `B` explicitly, and `B` depends on `A` implicitly. end example]
Enum members are named and scoped in a manner exactly analogous to fields within classes. The scope of an enum member is the body of its containing enum type. Within that scope, enum members can be referred to by their simple name. From all other code, the name of an enum member shall be qualified with the name of its enum type. Enum members do not have any declared accessibility—an enum member is accessible if its containing enum type is accessible.

### 21.4 The System.Enum type

The type `System.Enum` is the abstract base class of all enum types (this is distinct and different from the underlying type of the enum type), and the members inherited from `System.Enum` are available in any enum type. A boxing conversion (§11.3.1) exists from any enum type to `System.Enum`, and an unboxing conversion (§11.3.2) exists from `System.Enum` to any enum type.

Note that `System.Enum` is not itself an enum-type. Rather, it is a class-type from which all enum-types are derived. The type `System.Enum` inherits from the type `System.ValueType` (§11.1.1), which, in turn, inherits from type `object`. At run-time, a value of type `System.Enum` can be `null` or a reference to a boxed value of any enum type.

### 21.5 Enum values and operations

Each enum type defines a distinct type; an explicit enumeration conversion (§13.2.2) is required to convert between an enum type and an integral type, or between two enum types. The set of values that an enum type can take on is not limited by its enum members. In particular, any value of the underlying type of an enum can be cast to the enum type, and is a distinct valid value of that enum type.

Enum members have the type of their containing enum type (except within other enum member initializers: see §21.3). The value of an enum member declared in enum type `E` with associated value `v` is `(E)v`.

The following operators can be used on values of enum types: `==`, `!=`, `<`, `>`, `<=`, `>=` (§14.9.5), `+` (§14.7.4), `-` (§14.7.5), `&`, `^` (§14.10.2), `~` (§14.6.4), `++`, `--` (§14.5.9 and §14.6.5), and `sizeof` (§27.5.4).

Every enum type automatically derives from the class `System.Enum` (which, in turn, derives from `System.ValueType` and `object`). Thus, inherited methods and properties of this class can be used on values of an enum type.
22. Delegates

[Note: Delegates enable scenarios that some other languages have addressed with function pointers. However, unlike function pointers, delegates are object-oriented and type-safe. A delegate encapsulates both an object instance and a method. end note]

A delegate declaration defines a class that is derived from the class System.Delegate. A delegate instance encapsulates one or more methods, each of which is referred to as a callable entity. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Given a delegate instance and an appropriate set of arguments, one can invoke all of that delegate instance’s methods with that set of arguments.

[Note: An interesting and useful property of a delegate instance is that it does not know or care about the classes of the methods it encapsulates; all that matters is that those methods be consistent (§22.1) with the delegate’s type. This makes delegates perfectly suited for “anonymous” invocation. end note]

22.1 Delegate declarations

A delegate-declaration is a type-declaration (§16.6) that declares a new delegate type.

\[
\text{delegate-declaration:}
\begin{align*}
\text{attributes}_{\text{opt}} & \text{ delegate-modifiers}_{\text{opt}} \text{ delegate return-type identifier type-parameter-list}_{\text{opt}} \\
\text{ ( formal-parameter-list}_{\text{opt}} \text{ ) type-parameter-constraints-clauses}_{\text{opt}} ;
\end{align*}
\]

delegate-modifiers:

\begin{align*}
\text{delegate-modifier} \\
\text{delegate-modifiers} \text{ delegate-modifier}
\end{align*}

delegate-modifier:

\begin{align*}
\text{new} \\
\text{public} \\
\text{protected} \\
\text{internal} \\
\text{private}
\end{align*}

It is a compile-time error for the same modifier to appear multiple times in a delegate declaration.

A delegate declaration shall not supply a type-parameter-constraints-clauses unless it also supplies a type-parameter-list.

A delegate declaration that supplies a type-parameter-list is a generic delegate declaration (§25.4).

The new modifier is only permitted on delegates declared within another type, in which case it specifies that such a delegate hides an inherited member by the same name, as described in §17.2.2.

The public, protected, internal, and private modifiers control the accessibility of the delegate type. Depending on the context in which the delegate declaration occurs, some of these modifiers might not be permitted (§10.5.1).

The delegate’s type name is identifier.

The optional formal-parameter-list specifies the parameters of the delegate, and return-type indicates the return type of the delegate. A method and a delegate type are consistent if the following are true:

- For each parameter of the method:
If the parameter has no ref or out modifier, then the corresponding parameter of the delegate type has no ref or out modifier and there is an identity conversion or implicit reference conversion from the corresponding delegate parameter type to the method parameter type.

If the parameter has a ref or out modifier, then the corresponding parameter of the delegate type has the same modifier and the corresponding delegate parameter type is the same as the method parameter type.

- There is an identity conversion or implicit reference conversion from the return type of the method to the return type of the delegate type.

This definition of consistency allows covariance in return type and contravariance in parameter types.

Delegate types in C# are name equivalent, not structurally equivalent. Specifically, two delegate types that have the same parameter lists and return type are considered different delegate types. 

```csharp
delegate int D1(int i, double d);
class A {
    public static int M1(int a, double b) {...}
}
class B {
    delegate int D2(int c, double d);
    public static int M1(int f, double g) {...}
    public static void M2(int k, double l) {...}
    public static int M3(int g) {...}
    public static void M4(int g) {...}
    delegate object D3(string s);
    public static object M5(string s) {...}
    public static int[] M6(object o) {...}
}
```

The delegate types D1 and D2 are both consistent with the methods A.M1 and B.M1, since they have the same return type and parameter list; however, these delegate types are two different types, so they are not interchangeable. The delegate types D1 and D2 are not consistent with the methods B.M2, B.M3, and B.M4. The methods B.M5 and B.M6 are both consistent with delegate type D3.

The only way to declare a delegate type is via a delegate-declaration. A delegate type is a reference type that is derived from System.Delegate. Delegate types are implicitly sealed, so it is not permissible to derive any type from a delegate type. It is also not permissible to derive a non-delegate class type from System.Delegate. System.Delegate is not itself a delegate type; it is a class type from which all delegate types are derived.

C# provides special syntax for delegate instantiation and invocation. Except for instantiation, any operation that can be applied to a class or class instance can also be applied to a delegate class or instance, respectively. In particular, it is possible to access members of the System.Delegate type via the usual member access syntax.

The set of methods encapsulated by a delegate instance is called an invocation list. When a delegate instance is created (§22.2) from a single method, it encapsulates that method, and its invocation list contains only one entry. However, when two non-null delegate instances are combined, their invocation lists are concatenated—in the order left operand then right operand—to form a new invocation list, which contains two or more entries. An invocation list can never be empty.

Delegates are combined using the binary + (§14.7.4) and += operators (§14.14.2). A delegate can be removed from a combination of delegates, using the binary - (§14.7.5) and -= operators (§14.14.2). Delegates can be compared for equality (§14.9.8).

[Example: The following example shows the instantiation of a number of delegates, and their corresponding invocation lists:}
delegate void D(int x);
class Test
{
    public static void M1(int i) {...}
    public static void M2(int i) {...}
}

class Demo
{
    static void Main()
    {
        D cd1 = new D(Test.M1); // M1
        D cd2 = new D(Test.M2); // M2
        D cd3 = cd1 + cd2;    // M1 + M2
        D cd4 = cd3 + cd1;    // M1 + M2 + M1
        D cd5 = cd4 + cd3;    // M1 + M2 + M1 + M1 + M2
    }
}

When cd1 and cd2 are instantiated, they each encapsulate one method. When cd3 is instantiated, it has an invocation list of two methods, M1 and M2, in that order. cd4’s invocation list contains M1, M2, and M1, in that order. Finally, cd5’s invocation list contains M1, M2, M1, M1, and M2, in that order.

For more examples of combining (as well as removing) delegates, see §22.3.

### 22.2 Delegate instantiation

An instance of a delegate is created by a delegate-creation-expression (§14.5.10.3) or by an implicit conversion from an anonymous method or method group to a delegate type (§13.5 and §13.6). The newly created delegate instance then refers to one or more of:

- A static method.
- A target object (which cannot be null) and instance method.

When the argument of a delegate-creation-expression (§14.5.10.3) is a delegate instance the resulting delegate has the same invocation list as the argument, which may contain more than one entry.

[Example:

delegate void D(int x);
class Test
{
    public static void M1(int i) {...}
    public void M2(int i) {...}
}
class Demo
{
    static void Main()
    {
        D cd1 = new D(Test.M1); // static method
        Test t = new Test();
        D cd2 = new D(t.M2); // instance method
        D cd3 = new D(cd2);  // another delegate
    }
}

end example]

Once instantiated, delegate instances always refer to the same list of target objects and methods. [Note: Remember, when two delegates are combined, or one is removed from another, a new delegate results with its own invocation list; the invocation lists of the delegates combined or removed remain unchanged. end note]

### 22.3 Delegate invocation

C# provides special syntax for invoking a delegate. When a non-null delegate instance whose invocation list contains one entry, is invoked, it invokes the one method with the same arguments it was given, and returns the same value as the referred to method. (See §14.5.5.2 for detailed information on delegate
invocation.) If an exception occurs during the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, as if that method had directly called the method to which that delegate referred.

Invocation of a delegate instance whose invocation list contains multiple entries, proceeds by invoking each of the methods in the invocation list, synchronously, in order. Each method so called is passed the same set of arguments as was given to the delegate instance. If such a delegate invocation includes reference parameters (§17.5.1.2), each method invocation will occur with a reference to the same variable; changes to that variable by one method in the invocation list will be visible to methods further down the invocation list. If the delegate invocation includes output parameters or a return value, their final value will come from the invocation of the last delegate in the list. If an exception occurs during processing of the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, and any methods further down the invocation list are not invoked.

Attempting to invoke a delegate instance whose value is null results in an exception of type System.NullReferenceException.

[Example: The following example shows how to instantiate, combine, remove, and invoke delegates:

```csharp
using System;

delegate void D(int x);

class Test
{
    public static void M1(int i) {
        Console.WriteLine("Test.M1: "+i);
    }

    public static void M2(int i) {
        Console.WriteLine("Test.M2: "+i);
    }

    public void M3(int i) {
        Console.WriteLine("Test.M3: "+i);
    }
}
class Demo
{
    static void Main() {
        D cd1 = new D(Test.M1);
        cd1(-1);  // call M1
        D cd2 = new D(Test.M2);
        cd2(-2);  // call M2
        D cd3 = cd1 + cd2;
        cd3(10);  // call M1 then M2
        cd3 += cd1;  // call M1, M2, then M1
        cd3(20);    // call M1, M2, then M1
        Test t = new Test();
        D cd4 = new D(t.M3);
        cd3 += cd4;
        cd3(30);  // call M1, M2, M1, then M3
        cd3 -= cd1; // remove last M1
        cd3(40);  // call M1, M2, then M3
        cd3 -= cd1;
        cd3(50);  // call M1 then M2
        cd3 -= cd2;
        cd3(60);  // call M1
        cd3 -= cd2; // impossible removal is benign
        cd3(60);  // call M1
```
As shown in the statement `cd3 += cd1;`, a method can be present in an invocation list multiple times. In this case, it is simply invoked once per occurrence. In an invocation list such as this, when that method is removed, the last occurrence in the invocation list is the one actually removed.

Immediately prior to the execution of the final statement, `cd3 -= cd1;`, the delegate `cd3` refers to an empty invocation list. Attempting to subtract a delegate from an empty list (or to subtract a non-existent delegate from a non-empty list) is not an error.

The output produced is:

```
Test.M1: -1
Test.M2: -2
Test.M1: 10
Test.M2: 10
Test.M1: 20
Test.M2: 20
Test.M1: 20
Test.M1: 30
Test.M2: 30
Test.M1: 30
Test.M3: 30
Test.M1: 40
Test.M2: 40
Test.M3: 40
Test.M1: 50
Test.M2: 50
Test.M1: 60
Test.M1: 60
```

end example]
23. Exceptions

Exceptions in C# provide a structured, uniform, and type-safe way of handling both system level and application-level error conditions. [Note: The exception mechanism in C# is quite similar to that of C++, with a few important differences:

- In C#, all exceptions shall be represented by an instance of a class type derived from System.Exception. In C++, any value of any type can be used to represent an exception.
- In C#, a finally block (§15.10) can be used to write termination code that executes in both normal execution and exceptional conditions. C++ has no equivalent construct.
- In C#, system-level exceptions such as overflow, divide-by-zero, and null dereferences have well defined exception classes and are on a par with application-level error conditions.

end note]

23.1 Causes of exceptions

Exception can be thrown in two different ways.

- A throw statement (§15.9.5) throws an exception immediately and unconditionally. Control never reaches the statement immediately following the throw.
- Certain exceptional conditions that arise during the processing of C# statements and expression cause an exception in certain circumstances when the operation cannot be completed normally. [Example: An integer division operation (§14.7.2) throws a System.DivideByZeroException if the denominator is zero. end example] See §23.4 for a list of the various exceptions that can occur in this way.

23.2 The System.Exception class

The System.Exception class is the base type of all exceptions. This class has a few notable properties that all exceptions share:

- **Message** is a read-only property of type string that contains a human-readable description of the reason for the exception.
- **InnerException** is a read-only property of type Exception. If its value is non-null, it refers to the exception that caused the current exception. (That is, the current exception was raised in a catch block handling the type InnerException.) Otherwise, its value is null, indicating that this exception was not caused by another exception. (The number of exception objects chained together in this manner can be arbitrary.)

The value of these properties can be specified in calls to the instance constructor for System.Exception. [Note: The Standard Library provides two types that inherit directly from System.Exception: System.SystemException and System.ApplicationException. These classes are provided as a means to differentiate between exceptions defined by the system versus exceptions defined by applications, respectively. As such, it is recommended that exception classes be derived from one of these classes as appropriate, rather than from System.Exception directly. end note]

23.3 How exceptions are handled

Exceptions are handled by a try statement (§15.10).

When an exception occurs, the system searches for the nearest catch clause that can handle the exception, as determined by the run-time type of the exception. First, the current method is searched for a lexically
enclosing try statement, and the associated catch clauses of the try statement are considered in order. If that fails, the method that called the current method is searched for a lexically enclosing try statement that encloses the point of the call to the current method. This search continues until a catch clause is found that can handle the current exception, by naming an exception class that is of the same class, or a base class, of the run-time type of the exception being thrown. A catch clause that doesn’t name an exception class can handle any exception.

Once a matching catch clause is found, the system prepares to transfer control to the first statement of the catch clause. Before execution of the catch clause begins, the system first executes, in order, any finally clauses that were associated with try statements more nested that than the one that caught the exception.

If no matching catch clause is found, one of two things occurs:

- If the search for a matching catch clause reaches a static constructor (§17.11) or static field initializer, then a System.TypeInitializationException is thrown at the point that triggered the invocation of the static constructor. The inner exception of the System.TypeInitializationException contains the exception that was originally thrown.
- If the search for matching catch clauses reaches the code that initially started the thread, then execution of the thread is terminated. The impact of such termination is implementation-defined.

The behavior of uncaught exceptions that occur during finalizer execution is unspecified.

### 23.4 Common exception classes

24. Attributes

[Note: Much of the C# language enables the programmer to specify declarative information about the entities defined in the program. For example, the accessibility of a method in a class is specified by decorating it with the method-modifiers public, protected, internal, and private. end note]

C# enables programmers to invent new kinds of declarative information, called attributes. Programmers can then attach attributes to various program entities, and retrieve attribute information in a run-time environment. [Note: For instance, a framework might define a HelpAttribute attribute that can be placed on certain program entities (such as classes and methods) to provide a mapping from those program entities to their documentation. end note]

Attributes are defined through the declaration of attribute classes (§24.1), which can have positional and named parameters (§24.1.2). Attributes are associated with program entities using attribute specifications (§24.2), and can be retrieved at run-time as attribute instances (§24.3).

24.1 Attribute classes

A class that derives from the abstract class System.Attribute, whether directly or indirectly, is an attribute class. The declaration of an attribute class defines a new kind of attribute that can be placed on program entities. By convention, attribute classes are named with a suffix of Attribute. Uses of an attribute can either include or omit this suffix.

A generic class declaration shall not use System.Attribute as a direct or indirect base class. [Example: using System; public class B : Attribute {} public class C<T> : B {} // Error – generic cannot be an attribute]

24.1.1 Attribute usage

The attribute AttributeUsage (§24.4.1) is used to describe how an attribute class can be used. 

AttributeUsage has a positional parameter (§24.1.2) that enables an attribute class to specify the kinds of declarations on which it can be used. [Example: The example using System; [AttributeUsage(AttributeTargets.Class | AttributeTargets.Interface)] public class SimpleAttribute: Attribute {}]

defines an attribute class named SimpleAttribute that can be placed on class-declarations and interface-declarations only. The example

[Simple] class Class1 {...} [Simple] interface Interface1 {...}

shows several uses of the Simple attribute. Although this attribute is defined with the name SimpleAttribute, when this attribute is used, the Attribute suffix can be omitted, resulting in the short name Simple. Thus, the example above is semantically equivalent to the following

[SimpleAttribute] class Class1 {...} [SimpleAttribute] interface Interface1 {...}

end example]
AttributeUsage has a named parameter (§24.1.2), called AllowMultiple, which indicates whether the attribute can be specified more than once for a given entity. If AllowMultiple for an attribute class is true, then that class is a **multi-use attribute class**, and can be specified more than once on an entity. If AllowMultiple for an attribute class is false or it is unspecified, then that class is a **single-use attribute class**, and can be specified at most once on an entity.

[Example: The example

```csharp
using System;
[AttributeUsage(AttributeTargets.Class, AllowMultiple = true)]
public class AuthorAttribute: Attribute
{
    public AuthorAttribute(string name) {
        this.name = name;
    }
    public string Name { get { return name; } }  // get
    private string name;
}
```

defines a multi-use attribute class named AuthorAttribute. The example

```csharp
[Author("Brian Kernighan"), Author("Dennis Ritchie")]
class Class1 {...}
```

shows a class declaration with two uses of the Author attribute. end example]

AttributeUsage has another named parameter (§24.1.2), called Inherited, which indicates whether the attribute, when specified on a base class, is also inherited by classes that derive from that base class. If Inherited for an attribute class is true, then that attribute is inherited. If Inherited for an attribute class is false then that attribute is not inherited. If it is unspecified, its default value is true.

An attribute class X not having an AttributeUsage attribute attached to it, as in

```csharp
using System;
class X: Attribute { ... }
```

is equivalent to the following:

```csharp
using System;
[AttributeUsage(AttributeTargets.All, AllowMultiple = false, Inherited = true)]
class X: Attribute { ... }
```

### 24.1.2 Positional and named parameters

Attribute classes can have **positional parameters** and **named parameters**. Each public instance constructor for an attribute class defines a valid sequence of positional parameters for that attribute class. Each non-static public read-write field and property for an attribute class defines a named parameter for the attribute class. Both accessors of a property need to be public for the property to define a named parameter.

[Example: The example

```csharp
using System;
[AttributeUsage(AttributeTargets.Class)]
public class HelpAttribute: Attribute
{
    public HelpAttribute(string url) { // url is a positional parameter
        ...}
    public string Topic { // Topic is a named parameter
        get {...}
        set {...}
    }
    public string Url { get {...} }
}
```
defines an attribute class named HelpAttribute that has one positional parameter (string url) and one named parameter (string Topic). Although it is non-static and public, the property Url does not define a named parameter, since it is not read-write.

This attribute class might be used as follows:

```csharp
[Help("http://www.mycompany.com/.../Class1.htm")]
class Class1
{
}
[Help("http://www.mycompany.com/.../Misc.htm", Topic ="Class2")]
class Class2
{
}
```

24.1.3 Attribute parameter types

The types of positional and named parameters for an attribute class are limited to the attribute parameter types, which are:

- One of the following types: bool, byte, char, double, float, int, long, short, string.
- The type object.
- The type System.Type.
- An enum type, provided it has public accessibility and the types in which it is nested (if any) also have public accessibility.
- Single-dimensional arrays of the above types.

24.2 Attribute specification

Attribute specification is the application of a previously defined attribute to a program entity. An attribute is a piece of additional declarative information that is specified for a program entity. Attributes can be specified at global scope (to specify attributes on the containing assembly) and for type-declarations (§16.6), class-member-declarations (§17.1.4), struct-member-declarations (§18.2), interface-member-declarations (§20.2), enum-member-declarations (§21.1), accessor-declarations (§17.6.2), event-accessor-declarations (§17.7), elements of formal-parameter-lists (§17.5.1), and elements of type-parameter-lists (§25.1.1).

Attributes are specified in attribute sections. An attribute section consists of a pair of square brackets, which surround a comma-separated list of one or more attributes. The order in which attributes are specified in such a list, and the order in which sections attached to the same program entity are arranged, is not significant. For instance, the attribute specifications [A] [B], [B] [A], [A, B], and [B, A] are equivalent.
An attribute consists of an `attribute-name` and an optional list of positional and named arguments. The positional arguments (if any) precede the named arguments. A positional argument consists of an `attribute-argument-expression`; a named argument consists of a name, followed by an equal sign, followed by an `attribute-argument-expression`, which, together, are constrained by the same rules as simple assignment. The order of named arguments is not significant.

[Note: For convenience, a trailing comma is allowed in a `global-attribute-section` and an `attribute-section, just as one is allowed in an `array-initializer` (§19.6). end note]

The `attribute-name` identifies an attribute class. `type-name` shall refer to an attribute class. Otherwise, a compile-time error occurs. [Example: The example]

```csharp
class Class1 {}
[Class1] class Class2 {}  // Error
```
results in a compile-time error because it attempts to use `Class1` as an attribute class when `Class1` is not
an attribute class. end example]

When an attribute is placed at the global level, a `global-attribute-target-specifier` is required. The only
standardized `global-attribute-target` name is `assembly`. This target name shall only be used in the context
of an assembly.

The only standardized `attribute-target` names are `event`, `field`, `method`, `param`, `property`, `return`,
type, and `typevar`. These target names shall only be used in the following contexts:

- **event** — an event.
- **field** — a field. A field-like event (i.e., one without accessors) can also have an attribute with this
target.
- **method** — a constructor, finalizer, method, operator, property get and set accessors, and event add and
remove accessors. A field-like event (i.e., one without accessors) can also have an attribute with this
target.
- **param** — a property set accessor, event add and remove accessors, and a parameter in a constructor,
method, and operator.
- **property** — a property.
- **return** — a delegate, method, operator, and property get accessor.
- **type** — a delegate, class, struct, enum, and interface.
- **typevar** — a type parameter.

Certain contexts permit the specification of an attribute on more than one target. A program can explicitly
specify the target by including an `attribute-target-specifier`. In the absence of an `attribute-target-specifier`,
a reasonable default is applied, but an `attribute-target-specifier` can be used to affirm or override the default in
certain ambiguous cases (or just to affirm the default in non-ambiguous cases). Thus, typically,
`attribute-target-specifiers` can be omitted. The potentially ambiguous contexts are resolved as follows (using equality
as defined in §9.4.2):

- An attribute specified on a delegate declaration can apply either to the delegate being declared or to its
return value. In the absence of an `attribute-target-specifier`, the attribute applies to the delegate. An
`attribute-target` equal to `type` indicates that the attribute applies to the delegate; an `attribute-target`
equal to `return` indicates that the attribute applies to the return value.

- An attribute specified on a method declaration can apply either to the method being declared or to its
return value. In the absence of an `attribute-target-specifier`, the attribute applies to the method. An
`attribute-target` equal to `method` indicates that the attribute applies to the method; an `attribute-target`
equal to `return` indicates that the attribute applies to the return value.

- An attribute specified on an operator declaration can apply either to the operator being declared or to its
return value. In the absence of an `attribute-target-specifier`, the attribute applies to the operator. An
`attribute-target` equal to `method` indicates that the attribute applies to the operator; an `attribute-target`
equal to `return` indicates that the attribute applies to the return value.

- An attribute specified on a get accessor declaration for a property or indexer declaration can apply either
to the associated method or to its return value. In the absence of an `attribute-target-specifier`, the
attribute applies to the method. An `attribute-target` equal to `method` indicates that the attribute applies to
the method; an `attribute-target` equal to `return` indicates that the attribute applies to the return value.

- An attribute specified on a set accessor for a property or indexer declaration can apply either to the
associated method or to its lone implicit parameter. In the absence of an `attribute-target-specifier`, the
attribute applies to the method. An `attribute-target` equal to `method` indicates that the attribute applies to
the method; the presence of an `attribute-target` equal to `param` indicates that the attribute applies to the
parameter.
• An attribute specified on an event declaration that omits *event-accessor-declarations* can apply to the event being declared, to the associated field (if the event is not abstract), or to the associated add and remove methods. In the absence of an *attribute-target-specifier*, the attribute applies to the event declaration. An *attribute-target* equal to *event* indicates that the attribute applies to the event; an *attribute-target* equal to *field* indicates that the attribute applies to the field; and an *attribute-target* equal to *method* indicates that the attribute applies to the methods.

• In the case of an event declaration that does not omit *event-accessor-declarations*, an attribute specified on an add or remove accessor declaration for an event declaration can apply either to the associated method or to its lone parameter. In the absence of an *attribute-target-specifier*, the attribute applies to the method. An *attribute-target* equal to *method* indicates that the attribute applies to the method; an *attribute-target* equal to *param* indicates that the attribute applies to the parameter.

An implementation can accept other attribute target specifiers, the purposes of which are implementation-defined. However, an implementation that does not recognize such a target, shall issue a warning.

By convention, attribute classes are named with a suffix of *Attribute*. An *attribute-name* can either include or omit this suffix. Specifically, an *attribute-name* is resolved as follows:

• If the right-most identifier of the *attribute-name* is a verbatim identifier (§9.4.2), then the *attribute-name* is resolved as a *type-name* (§10.8). If the result is not a type derived from *System.Attribute*, a compile-time error occurs.

• Otherwise,
  o The *attribute-name* is resolved as a *type-name* (§10.8) except any errors are suppressed. If this resolution is successful and results in a type derived from *System.Attribute* then the type is the result of this step.
  o The characters *Attribute* are appended to the right-most identifier in the *attribute-name* and the resulting string of tokens is resolved as a *type-name* (§10.8) except any errors are suppressed. If this resolution is successful and results in a type derived from *System.Attribute* then the type is the result of this step.

If exactly one of the two steps above results in a type derived from *System.Attribute*, then that type is the result of the *attribute-name*. Otherwise a compile-time error occurs.

[Example: Informally, when attempting to resolve an *attribute-name*, if an attribute class is found both with and without the *Attribute* suffix, an ambiguity is present, and a compile-time error is issued. If the *attribute-name* is spelled such that its right-most *identifier* is a verbatim identifier (§9.4.2), then only an attribute without a suffix is matched, thus enabling such an ambiguity to be resolved. The example

```csharp
using System;
[AttributeUsage(AttributeTargets.All)]
public class X: Attribute
{
}
[AttributeUsage(AttributeTargets.All)]
public class XAttribute: Attribute
{
}
[X]     // error: ambiguity
class Class1 {}
[XAttribute]  // refers to XAttribute
class Class2 {}
[@X]     // refers to X
class Class3 {}
[@XAttribute]  // refers to XAttribute
class Class4 {}
```

shows two attribute classes named *X* and *XAttribute*. The attribute reference [*X*] is ambiguous, since it could refer to either *X* or *XAttribute*. Using a verbatim identifier allows the exact intent to be specified in such rare cases. The attribute reference [*XAttribute*] is not ambiguous (although it would be if there were
an attribute class named XAttributeAttribute!). If the declaration for class X is removed, then both attributes refer to the attribute class named XAttribute, as follows:

```csharp
using System;

[AttributeUsage(AttributeTargets.All)]
public class XAttribute: Attribute
{

[X]   // refers to XAttribute
class Class1 {}

[XAttribute]  // refers to XAttribute
class Class2 {}

[@X]      // error: no attribute named “X”
class Class3 {}

end example]
```

It is a compile-time error to use a single-use attribute class more than once on the same entity. [Example:]

The example

```csharp
using System;

[AttributeUsage(AttributeTargets.Class)]
public class HelpStringAttribute: Attribute
{
    string value;
    public HelpStringAttribute(string value) {
        this.value = value;
    }
    public string Value { get {...} }
}

[HelpString("Description of Class1")]
[HelpString("Another description of Class1")]
public class Class1 {}
```

results in a compile-time error because it attempts to use HelpString, which is a single-use attribute class, more than once on the declaration of Class1. end example]

An expression E is an attribute-argument-expression if all of the following statements are true:

- The type of E is an attribute parameter type (§24.1.3).
- At compile-time, the value of E can be resolved to one of the following:
  - A constant value.
  - A typeof-expression (§14.5.11) specifying a non-generic type, a closed constructed type (§25.5.2), or an unbound generic type (§25.5).
  - A one-dimensional array of attribute-argument-expressions.

[Example:

```csharp
using System;

[AttributeUsage(AttributeTargets.Class)]
public class MyAttribute: Attribute
{
    public int P1 {
        get {...}
        set {...}
    }

    public Type P2 {
        get {...}
        set {...}
    }
}
```
The attributes of a type declared in multiple parts are determined by combining, in an unspecified order, the attributes of each of its parts. If the same attribute is placed on multiple parts, it is equivalent to specifying that attribute multiple times on the type. [Example: The two parts:

```
[Attr1, Attr2("hello")]
partial class A {}
[Attr3, Attr2("goodbye")]
partial class A {}
```

are equivalent to the following single declaration:

```
[Attr1, Attr2("hello"), Attr3, Attr2("goodbye")]
class A {}
```

end example]

Attributes on type parameters combine in the same way.

### 24.3 Attribute instances

An attribute instance is an instance that represents an attribute at run-time. An attribute is defined with an attribute class, positional arguments, and named arguments. An attribute instance is an instance of the attribute class that is initialized with the positional and named arguments.

Retrieval of an attribute instance involves both compile-time and run-time processing, as described in the following subclauses.

#### 24.3.1 Compilation of an attribute

The compilation of an attribute with attribute class T, positional-argument-list P, named-argument-list N, and specified on a program entity E is compiled into an assembly A via the following steps:

- Follow the compile-time processing steps for compiling an object-creation-expression of the form `new T(P)`. These steps either result in a compile-time error, or determine an instance constructor on T that can be invoked at run-time. Call this instance constructor C.
- If C does not have public accessibility, then a compile-time error occurs.
- For each named-argument Arg in N:
  - Let Name be the identifier of the named-argument Arg.
  - Name shall identify a non-static read-write public field or property on T. If T has no such field or property, then a compile-time error occurs.

```csharp
public object P3 {
    get {...}
    set {...}
}

[My(P1 = 1234, P3 = new int[]{1, 3, 5}, P2 = typeof(float))] class MyClass {}

class C<T> {
    [My(P2 = typeof(T))]    // Error – T not a closed type.
    int x1;
    [My(P2 = typeof(C<T>))] // Error – C<T> not a closed type.
    int x2;
    [My(P2 = typeof(C<int>))] // Ok
    int x3;
    [My(P2 = typeof(C<>))]  // Ok
    int x4;
}
end example
```
• Store the following information (for run-time instantiation of the attribute) in the assembly output by the compiler as a result of compiling the program containing the attribute: the attribute class T, the instance constructor C on T, the positional-argument-list P, the named-argument-list N, and the associated program entity E, with the values resolved completely at compile-time.

24.3.2 Run-time retrieval of an attribute instance

The attribute instance represented by T, C, P, and N, and associated with E can be retrieved at run-time from the assembly A using the following steps:

• Follow the run-time processing steps for executing an object-creation-expression of the form new T(P), using the instance constructor C and values as determined at compile-time. These steps either result in an exception, or produce an instance of T. Call this instance O.

• For each named-argument Arg in N, in order:
  o Let Name be the identifier of the named-argument Arg. If Name does not identify a non-static public read-write field or property on O, then an exception is thrown.
  o Let Value be the result of evaluating the attribute-argument-expression of Arg.
  o If Name identifies a field on O, then set this field to the value Value.
  o Otherwise, Name identifies a property on O. Set this property to the value Value.
  o The result is O, an instance of the attribute class T that has been initialized with the positional-argument-list P and the named-argument-list N.

[Note: The format for storing T, C, P, N (and associating it with E) in A and the mechanism to specify E and retrieve T, C, P, N from A (and hence how an attribute instance is obtained at runtime) is beyond the scope of this standard. end note]

[Example: In an implementation of the CLI, the Help attribute instances in the assembly created by compiling the example program in §24.1.2 can be retrieved with the following program:

```csharp
using System;
using System.Reflection;
public sealed class InterrogateHelpUrls
{
    public static void Main(string[] args) {
        Type helpType = typeof(HelpAttribute);
        string assemblyName = args[0];
        foreach (Type t in Assembly.Load(assemblyName).GetTypes()) {
            Console.WriteLine("Type : {0}", t.ToString());
            HelpAttribute[] helpers = (HelpAttribute[])t.GetCustomAttributes(helpType, false);
            for (int at = 0; at != helpers.Length; at++) {
                Console.WriteLine("Url  : {0}", helpers[at].Url);
            }
        }
    }
}
end example]

24.4 Reserved attributes

The following attributes affect the language, as stated:

• System.AttributeUsageAttribute (§24.4.1), which is used to describe the ways in which an attribute class can be used.

• System.Diagnostics.ConditionalAttribute (§24.4.2), is a multi-use attribute class which is used to define conditional methods and conditional attribute classes. This attribute indicates a condition by testing a conditional compilation symbol.
• System.ObsoleteAttribute (§24.4.3), which is used to mark a member as obsolete.

**24.4.1 The AttributeUsage attribute**

The attribute `AttributeUsage` is used to describe the manner in which the attribute class can be used. A class that is decorated with the `AttributeUsage` attribute shall derive from `System.Attribute`, either directly or indirectly. Otherwise, a compile-time error occurs.

*Note: For an example of using this attribute, see §24.1.1. end note*

**24.4.2 The Conditional attribute**

The attribute `Conditional` enables the definition of *conditional methods* and *conditional attribute classes.*

**24.4.2.1 Conditional methods**

A method decorated with the `Conditional` attribute is a conditional method. Each conditional method is thus associated with the conditional compilation symbols declared in its `Conditional` attributes. *[Example:]*

```csharp
using System.Diagnostics;
using System.Diagnostics;
class Eg
{
    [Conditional("ALPHA")]
    [Conditional("BETA")]
    public static void M() {
        //...
    }
}
```

declares `Eg.M` as a conditional method associated with the two conditional compilation symbols `ALPHA` and `BETA. end example]*

A call to a conditional method is included if one or more of its associated conditional compilation symbols is defined at the point of call, otherwise the call is omitted.

A conditional method is subject to the following restrictions:

• The conditional method shall be a method in a *class-declaration or struct-declaration.* A compile-time error occurs if the `Conditional` attribute is specified on an interface method.

• The conditional method shall have a return type of `void`.

• The conditional method shall not be marked with the `override` modifier. A conditional method can be marked with the `virtual` modifier, however. Overrides of such a method are implicitly conditional, and shall not be explicitly marked with a `Conditional` attribute.

• The conditional method shall not be an implementation of an interface method. Otherwise, a compile-time error occurs.

In addition, a compile-time error occurs if a conditional method is used in a *delegate-creation-expression.*

*[Example: The example]*

```csharp
#define DEBUG
using System.Diagnostics;
using System.Diagnostics;
class Class1
{
    [Conditional("DEBUG")]
    public static void M()
    {
        Console.WriteLine("Executed Class1.M");
    }
}
```
class Class2
{
    public static void Test()
    {
        Class1.M();
    }
}

declares Class1.M as a conditional method. Class2's Test method calls this method. Since the
conditional compilation symbol DEBUG is defined, if Class2.Test is called, it will call M. If the symbol
DEBUG had not been defined, then Class2.Test would not call Class1.M. end example]

It is important to understand that the inclusion or exclusion of a call to a conditional method is controlled by
the conditional compilation symbols at the point of the call. [Example: In the following code

// Begin class1.cs
using System;
using System.Diagnostics;
class Class1
{
    [Conditional("DEBUG")]
    public static void F()
    {
        Console.WriteLine("Executed Class1.F");
    }
}
// End class1.cs

// Begin class2.cs
#define DEBUG
class Class2
{
    public static void G()
    {
        Class1.F(); // F is called
    }
}
// End class2.cs

// Begin class3.cs
#undef DEBUG
class Class3
{
    public static void H()
    {
        Class1.F(); // F is not called
    }
}
// End class3.cs

the classes Class2 and Class3 each contain calls to the conditional method Class1.F, which is
conditional based on whether or not DEBUG is defined. Since this symbol is defined in the context of Class2
but not Class3, the call to F in Class2 is included, while the call to F in Class3 is omitted. end example]

The use of conditional methods in an inheritance chain can be confusing. Calls made to a conditional
method through base, of the form base.M, are subject to the normal conditional method call rules.
[Example: In the following code

// Begin class1.cs
using System;
using System.Diagnostics;

```csharp
class Class2
{
    public static void Test()
    {
        Class1.M();
    }
}
```
class Class1
{
    [Conditional("DEBUG")]
    public virtual void M()
    {
        Console.WriteLine("Class1.M executed");
    }
}

// End class1.cs

// Begin class2.cs
using System;
class Class2: Class1
{
    public override void M()
    {
        Console.WriteLine("Class2.M executed");
        base.M(); // base.M is not called!
    }
}

// End class2.cs

// Begin class3.cs
#define DEBUG
using System;
class Class3
{
    public static void Test()
    {
        Class2 c = new Class2();
        c.M(); // M is called
    }
}

// End class3.cs

Class2 includes a call to the M defined in its base class. This call is omitted because the base method is conditional based on the presence of the symbol DEBUG, which is undefined. Thus, the method writes to the console "Class2.M executed" only. Judicious use of pp-declarations can eliminate such problems. end example

24.4.2.2 Conditional attribute classes

An attribute class (§24.1) decorated with one or more Conditional attributes is a conditional attribute class. A conditional attribute class is thus associated with the conditional compilation symbols declared in its Conditional attributes.

[Example:
using System;
using System.Diagnostics;
[Conditional("ALPHA")]
[Conditional("BETA")]
public class TestAttribute : Attribute {}

declares TestAttribute as a conditional attribute class associated with the conditional compilations symbols ALPHA and BETA. end example]

Attribute specifications (§24.2) of a conditional attribute are included if one or more of its associated conditional compilation symbols is defined at the point of specification, otherwise the attribute specification is omitted.
It is important to note that the inclusion or exclusion of an attribute specification of a conditional attribute class is controlled by the conditional compilation symbols at the point of the specification. [Example: In the example

File test.cs:
  using System;
  using System.Diagnostics;
  [Conditional("DEBUG")]
  public class TestAttribute : Attribute {}

File class1.cs:
  #define DEBUG
  [Test] // TestAttribute is specified
  class Class1 {}

File class2.cs:
  #undef DEBUG
  [Test] // TestAttribute is not specified
  class Class2 {}
the classes Class1 and Class2 are each decorated with attribute Test, which is conditional based on whether or not DEBUG is defined. Since this symbol is defined in the context of Class1 but not Class2, the specification of the Test attribute on Class1 is included, while the specification of the Test attribute on Class2 is omitted. end example]

24.4.3 The Obsolete attribute
The attribute Obsolete is used to mark types and members of types that should no longer be used.

If a program uses a type or member that is decorated with the Obsolete attribute, then the compiler shall issue a warning or error in order to alert the developer, so the offending code can be fixed. Specifically, the compiler shall issue a warning if no error parameter is provided, or if the error parameter is provided and has the value false. The compiler shall issue a compile-time error if the error parameter is specified and has the value true.

[Example: In the following code

    [Obsolete("This class is obsolete; use class B instead")]
    class A
    {
        public void F() {}
    }
    class B
    {
        public void F() {}
    }
    class Test
    {
        static void Main()
        {
            A a = new A(); // warning
            a.F();
        }
    }

the class A is decorated with the Obsolete attribute. Each use of A in Main results in a warning that includes the specified message, “This class is obsolete; use class B instead.” end example]
25. Generics

25.1 Generic class declarations

A generic class declaration is a declaration of a class that requires type arguments to be supplied in order to form runtime types.

[Note: A class declaration (§17.1), can optionally define type parameters and their associated constraints:

```
class-declaration:
  attributes_opt  class-modifiers_opt  partial_opt  class  identifier  type-parameter-list_opt
  class-base_opt  type-parameter-constraints-clauses_opt  class-body ; opt
```

A class declaration shall not supply type-parameter-constraints-clauses (§25.7) unless it also supplies a type-parameter-list (§25.1.1).

A class declaration that supplies a type-parameter-list is a generic class declaration. end note]

Any class nested inside a generic class declaration or a generic struct declaration (§25.2) is itself a generic class declaration, since type parameters for the containing type shall be supplied to create a constructed type.

Generic class declarations follow the same rules as non-generic class declarations except where noted. Generic class declarations can be nested inside non-generic class declarations.

A generic class is referenced using a constructed type (§25.5). [Example: Given the generic class declaration

```
class List<T> {}
```

some examples of constructed types are `List<T>`, `List<int>` and `List<List<string>>`. end example]

A constructed type that uses one or more type parameters, such as `List<T>`, is called an open constructed type (§25.5). A constructed type that uses no type parameters, such as `List<int>`, is called a closed constructed type (§25.5).

Generic types can be "overloaded" on the number of type parameters; that is two type declarations within the same namespace or outer type declaration can use the same identifier as long as they have a different number of type parameters.

```
class C {}
class C<V> {}  // OK
struct C<U,V> {}  // OK
class C<A,B> {}  // Error, C with two type parameters defined twice
```

The type lookup rules used during type name resolution (§10.8), simple name resolution (§14.5.2) and member access (§14.5.4) respect the number of type parameters.

The base interfaces of a generic class declaration shall satisfy the uniqueness rule described in §25.3.1.

25.1.1 Type parameters

Type parameters can be supplied in a class declaration. Each type parameter is a simple identifier that denotes a placeholder for a type argument supplied to create a constructed type. A type parameter is a formal placeholder for a type that will be supplied later. By contrast, a type argument (§25.5.1) is the runtime type that is substituted for the type parameter when a constructed type is created.

```
type-parameter-list:
  <  type-parameters  >
```
Each type parameter in a class declaration defines a name in the declaration space (§10.3) of that class. Thus, it cannot have the same name as another type parameter or a member declared in that class. A type parameter shall not have the same name as the type itself.

The scope (§10.7) of a type parameter on a class includes the class-base, type-parameter-constraints-clauses, and class-body. Unlike members of a class, this scope does not extend to derived classes. Within its scope, a type parameter can be used as a type.

Since a type parameter can be instantiated with many different runtime type arguments, type parameters have slightly different operations and restrictions than other types. [Note: These include the following:

- A type parameter cannot be used directly to declare a base class or interface (§17.1.2).
- The rules for member lookup on type parameters depend on the constraints, if any, applied to the type parameter. They are detailed in §25.7.2.
- The available conversions for a type parameter depend on the constraints, if any, applied to the type parameter. They are detailed in §25.7.4.
- The literal null cannot be converted to a type given by a type parameter, except if the type parameter is known to be a reference type (§25.7.4). However, a default value expression (§14.5.14) can be used instead.
- A new expression (§14.5.10.1) can only be used with a type parameter if the type parameter is constrained by a constructor-constraint or the value type constraint (§25.7).
- A type parameter cannot be used anywhere within an attribute (§24.2).
- A type parameter cannot be used in a member access or type name to identify a static member or a nested type (§10.8, §14.5.4).
- In unsafe code, a type parameter cannot be used as an unmanaged-type (§27.2).]

As a type, type parameters are purely a compile-time construct. At run-time, each type parameter is bound to a run-time type that was specified by supplying a type argument to the generic type declaration. Thus, the type of a variable declared with a type parameter will, at run-time, be a closed constructed type (§25.5.2). The run-time execution of all statements and expressions involving type parameters uses the runtime type that was supplied as the type argument for that parameter.

25.1.2 The instance type

Each class declaration has an associated constructed type, the instance type. For a generic class declaration, the instance type is formed by creating a constructed type (§25.5) from the type declaration, with each of the supplied type arguments being the corresponding type parameter. Since the instance type uses the type parameters, it can only be used where the type parameters are in scope; that is, inside the class declaration. The instance type is the type of this for code written inside the class declaration. For non-generic classes, the instance type is simply the declared class. [Example: The following shows several class declarations along with their instance types:

```csharp
class A<T>       // instance type: A<T>
{
    class B {}      // instance type: A<T>.B
    class C<U> {}    // instance type: A<T>.C<U>
};
class D {}       // instance type: D
```
25.1.3 Members of generic classes

All members of a generic class can use type parameters from any enclosing class, either directly or as part of a constructed type. When a particular closed constructed type (§25.5.2) is used at run-time, each use of a type parameter is replaced with the runtime type argument supplied to the constructed type. [Example:

```csharp
class C<V>
{
    public V F1;
    public C<V> F2 = null;
    public C(V x) {
        this.F1 = x;
        this.F2 = this;
    }
}
class Application
{
    static void Main() {
        C<int> x1 = new C<int>(1);
        Console.WriteLine(x1.F1);  // Prints 1
        C<double> x2 = new C<double>(3.1415);
        Console.WriteLine(x2.F1);  // Prints 3.1415
    }
}
```

end example]

Within instance function members, the type of this is the instance type (§25.1.2) of the containing declaration.

Apart from the use of type parameters as types, members in generic class declarations follow the same rules as members of non-generic classes. Additional rules that apply to particular kinds of members are discussed in the following subclauses.

25.1.4 Static fields in generic classes

A static variable in a generic class declaration is shared amongst all instances of the same closed constructed type (§25.5.2), but is not shared amongst instances of different closed constructed types. These rules apply regardless of whether the type of the static variable involves any type parameters or not. [Example:

```csharp
class C<V>
{
    static int count = 0;
    public C() {
        count++;
    }
    public static int Count {
        get { return count; }
    }
}
class Application
{
    static void Main() {
        C<int> x1 = new C<int>();
        Console.WriteLine(C<int>.Count);  // Prints 1
        C<double> x2 = new C<double>();
        Console.WriteLine(C<double>.Count); // Prints 1
    }
}
```

end example]
C# LANGUAGE SPECIFICATION

```csharp
C<int> x3 = new C<int>();
Console.WriteLine(C<int>.Count);  // Prints 2
}
```

**25.1.5 Static constructors in generic classes**

A static constructor in a generic class is used to initialize static fields and to perform other initialization for each different closed constructed type that is created from that generic class declaration. The type parameters of the generic type declaration are in scope, and can be used, within the body of the static constructor.

A new closed constructed class type is initialized the first time that either:

- An instance of the closed constructed type is created.
- Any of the static members of the closed constructed type are referenced.

To initialize a new closed constructed class type, first a new set of static fields (§25.1.4) for that particular closed constructed type is created. Each of the static fields is initialized to its default value (§12.2). Next, the static field initializers (§17.4.5.1) are executed for those static fields. Finally, the static constructor is executed.

Because the static constructor is executed exactly once for each closed constructed class type, it is a convenient place to enforce run-time checks on the type parameter that cannot be checked at compile-time via constraints (§25.7). [Example: The following type uses a static constructor to enforce that the type argument is an enum:]

```csharp
class Gen<T> where T: struct
{
    static Gen() {
        if (!typeof(T).IsEnum) {
            throw new ArgumentException("T must be an enum");
        }
    }
}
```

**25.1.6 Accessing protected members**

[Note: The accessibility domain (§10.5.2) of a protected member declared in a generic class includes the program text of all class declarations derived from any type constructed from that generic class. In the example:]

```csharp
class C<T>
{
    protected static T x;
}
class D: C<string>
{
    static void Main() {
        C<int>.x = 5;
    }
}
```

The reference to protected member `C<int>.x` in `D` is valid even though the class `D` derives from `C<string>`.

*end note*

Within a generic class declaration, access to inherited protected instance members (§10.5.3) is permitted through an instance of any class type constructed from the generic class. [Example: In the following code
class C<T>
{
    protected T x;
}

class D<T>: C<T>
{
    static void F()
    {
        D<T> dt = new D<T>();
        D<int> di = new D<int>();
        D<string> ds = new D<string>();
        dt.x = default(T);
        di.x = 123;
        ds.x = "test";
    }
}

the three assignments to \textit{x} are permitted because they all take place through instances of class types constructed from the generic type. \textit{end example}

\subsection*{25.1.7 Overloading in generic classes}

Methods, constructors, indexers, and operators within a generic class declaration can be overloaded. While signatures as declared must be unique, it is possible that substitution of type arguments results in identical signatures. The tie-breaking rules of overload resolution will pick the most specific one.

\textit{Example:} The following examples show overloads that are valid according to this rule:

\begin{verbatim}
interface I1<T> {...}
interface I2<T> {...}

class G1<U>
{
    long F1(U u) {...}  // Overload resolution for G<int>.F1
    int F1(int i) {...}  // will pick non-generic
    void F3(I1<U> a) {...}  // Valid overload
    void F3(I2<U> a) {...}
}
class G2<U, V>
{
    void F5(U u, V v) {...}  // Overload resolution for G2<int, int>
    void F5(V v, U u) {...}  // fail
    void F6(U u, I1<V> v) {...}  // Valid, overload resolution on G2<I1<int>, int>
    void F6(I1<V> v, U u) {...}  // is ambiguous
    void F7(U u1, I1<V> v2) {...}  // Valid overload
    void F7(V v1, U u2) {...}
    void F8(ref U u) {...}  // Valid overload
    void F8(out V v) {...}
}
\end{verbatim}

\textit{end example}

\subsection*{25.1.8 Parameter array methods and type parameters}

Type parameters can be used in the type of a parameter array. \textit{Example:} Given the declaration

\begin{verbatim}
class C<V>
{
    static void F(int x, int y, params V[] args) { ... }
}
\end{verbatim}

the following invocations of the expanded form of the method:
C# LANGUAGE SPECIFICATION

C<int>.F(10, 20);
C<object>.F(10, 20, 30, 40);
C<string>.F(10, 20, "hello", "goodbye");
correspond exactly to:
C<int>.F(10, 20, new int[]{})
C<object>.F(10, 20, new object[]{30, 40})
C<string>.F(10, 20, new string[]{"hello", "goodbye"})

end example

25.1.9 Overriding and generic classes

Function members in generic classes can override function members in base classes, as usual. When determining the overridden base member, the members of the base classes shall be determined by substituting type arguments, as described in §25.5.4. Once the members of the base classes are determined, the rules for overriding are the same as for non-generic classes.

[Example: The following example demonstrates how the overriding rules work in the presence of generics:

```csharp
abstract class C<T>
{
    public virtual T F() {...}
    public virtual C<T> G() {...}
    public virtual void H(C<T> x) {...}
}
class D: C<string>
{
    public override string F() {...}   // Ok
    public override C<string> G() {...} // Ok
    public override void H(C<int> x) {...} // Error, should be C<string>
}
class E<T, U>: C<U>
{
    public override U F() {...}     // Ok
    public override C<U> G() {...}    // Ok
    public override void H(C<T> x) {...}  // Error, should be C<U>
}
end example]

25.1.10 Operators in generic classes

Generic class declarations can define operators, following the same rules as non-generic class declarations. The instance type (§25.1.2) of the class declaration shall be used in the declaration of operators in a manner analogous to the normal rules for operators, as follows:

• A unary operator shall take a single parameter of the instance type. The unary ++ and -- operators shall return the instance type or a type derived from the instance type.

• At least one of the parameters of a binary operator shall be of the instance type.

• Either the parameter type or the return type of a conversion operator shall be of the instance type.

[Example: The following shows some examples of valid operator declarations in a generic class:

```csharp
class X<T>
{
    public static X<T> operator ++(X<T> operand) {...}
    public static int operator *(X<T> op1, int op2) {...}
    public static explicit operator X<T>(T value) {...}
}
end example]
For a conversion operator that converts from a source type $S$ to a target type $T$, when the rules specified in §17.9.3 are applied, any type parameters associated with $S$ or $T$ are considered to be unique types that have no inheritance relationship with other types, and any constraints on those type parameters are ignored.

[Example: In the following code]

```csharp
class C<T> {...}
class D<T>: C<T>
{
    public static implicit operator C<int>(D<T> value) {...}  // Ok
    public static implicit operator C<string>(D<T> value) {...}  // Ok
    public static implicit operator C<T>(D<T> value) {...}   // Error
}
```

the first two operator declarations are permitted because, for the purposes of §17.9.3, $T$, and `int` and `string`, respectively, are considered unique types with no relationship. However, the third operator is an error because $C<T>$ is the base class of $D<T>$. end example]

It is possible to declare operators that, for some type arguments, specify conversions that already exist as pre-defined conversions. [Example: In the following code]

```csharp
structConvertible<T>
{
    public static implicit operator Convertible<T>(T value) {...}
    public static explicit operator T(Convertible<T> value) {...}
}
```

when type `object` is specified as a type argument for $T$, the second operator declares a conversion that already exists (an implicit, and therefore also an explicit, conversion exists from any type to type `object`). end example]

In cases where a pre-defined conversion exists between two types, any user-defined conversions between those types are ignored. Specifically:

- If a pre-defined implicit conversion (§13.1) exists from type $S$ to type $T$, all user-defined conversions (implicit or explicit) from $S$ to $T$ are ignored.
- If a pre-defined explicit conversion (§13.2) exists from type $S$ to type $T$, any user-defined explicit conversions from $S$ to $T$ are ignored. However, user-defined implicit conversions from $S$ to $T$ are still considered.

[Example: For all types but `object`, the operators declared by the `Convertible<T>` type above do not conflict with pre-defined conversions. For example:]

```csharp
void F(int i, Convertible<int> n) {
    i = n;        // Error
    i = (int)n;       // User-defined explicit conversion
    n = i;         // User-defined implicit conversion
    n = (Convertible<int>)i; // User-defined implicit conversion
}
```

However, for type `object`, pre-defined conversions hide the user-defined conversions in all cases but one:

```csharp
void F(object o, Convertible<object> n) {
    o = n;        // Pre-defined boxing conversion
    o = (object)n;      // Pre-defined boxing conversion
    n = o;         // User-defined implicit conversion
    n = (Convertible<object>)o; // Pre-defined unboxing conversion
}
```

end example]

### 25.1.11 Nested types in generic classes

A generic class declaration can contain nested type declarations. The type parameters of the enclosing class can be used within the nested types. A nested type declaration can contain additional type parameters that apply only to the nested type.
Every type declaration contained within a generic class declaration is implicitly a generic type declaration. When writing a reference to a type nested within a generic type, the containing constructed type, including its type arguments, shall be named. However, from within the outer class, the nested type can be used without qualification; the instance type of the outer class can be implicitly used when constructing the nested type. [Example: The following example shows three different correct ways to refer to a constructed type created from Inner; the first two are equivalent:

```csharp
class Outer<T>
{
    class Inner<U>
    {
        public static void F(T t, U u) {...}
    }
    static void F(T t) {
        Outer<T>.Inner<string>.F(t, "abc");  // These two statements have the same effect
        Outer<int>.Inner<string>.F(3, "abc");  // This type is different
        Outer.Inner<string>.F(t, "abc");  // Error, Outer needs type arg
    }
}
```

Although it is bad programming style, a type parameter in a nested type can hide a member or type parameter declared in the outer type. [Example:]

```csharp
class Outer<T>
{
    class Inner<T>  // Valid, hides Outer’s T
    {
        public T t;  // Refers to Inner’s T
    }
}
```

25.2 Generic struct declarations

[Note: A struct declaration (§18.1), can optionally define type parameters and their associated constraints:

```
struct-declaration:
    attributesopt struct-modifiersopt partialopt struct identifier type-parameter-listopt
    struct-interfacesopt type-parameter-constraints-clausesopt struct-body ;opt
```

end note]

The rules for generic class declarations (§25.1 and its subclauses) apply equally to generic struct declarations, as do the exceptions noted in §18.3.

25.3 Generic interface declarations

[Note: An interface declaration (§20.1), can optionally define type parameters and their associated constraints:

```
interface-declaration:
    attributesopt interface-modifiersopt partialopt interface identifier type-parameter-listopt
    interface-baseopt type-parameter-constraints-clausesopt interface-body ;opt
```

end note]
Except where noted below, generic interface declarations follow the same rules as non-generic interface declarations.

Each type parameter in an interface declaration defines a name in the declaration space (§10.3) of that interface. The scope (§10.7) of a type parameter on an interface includes the interface-base, type-parameter-constraints-clauses, and interface-body. Within its scope, a type parameter can be used as a type. The same restrictions apply to type parameters on interfaces as apply to type parameter on classes (§25.1.1).

### 25.3.1 Uniqueness of implemented interfaces

The interfaces implemented by a generic type declaration shall remain unique for all possible constructed types. Without this rule, it would be impossible to determine the correct method to call for certain constructed types. *Example:* Suppose a generic class declaration were permitted to be written as follows:

```java
interface I<T>
{
    void F();
}
class X<U, V>: I<U>, I<V>     // Error: I<U> and I<V> conflict
{
    void I<U>.F() {...}
    void I<V>.F() {...}
}
```

Were this permitted, it would be impossible to determine which code to execute in the following case:

```java
I<int> x = new X<int,int>();
x.F();
```

*end example*

To determine if the interface list of a generic type declaration is valid, the following steps are performed:

- Let $L$ be the list of interfaces directly specified in a generic class, struct, or interface declaration $C$.
- Add to $L$ any base interfaces of the interfaces already in $L$.
- Remove any duplicates from $L$.
- If any possible constructed type created from $C$ would, after type arguments are substituted into $L$, cause two interfaces in $L$ to be identical, then the declaration of $C$ is invalid. Constraint declarations are not considered when determining all possible constructed types.

*Note:* In the class declaration $X$ above, the interface list $L$ consists of $I<U>$ and $I<V>$. The declaration is invalid because any constructed type with $U$ and $V$ being the same type would cause these two interfaces to be identical types. *end note*

*Example:* It is possible for interfaces specified at different inheritance levels to unify:

```java
interface I<T>
{
    void F();
}
class Base<U>: I<U>
{
    void I<U>.F() {...}
}
class Derived<U, V>: Base<U>, I<V>     // Ok
{
    void I<V>.F() {...}
}
```

This code is valid even though $\text{Derived}<U, V>$ implements both $I<U>$ and $I<V>$. The code

```java
I<int> x = new X<int,int>();
x.F();
```

*end example*
invokes the method in Derived, since Derived<int, int> effectively re-implements I<int> (§20.4.4).

end example]

25.3.2 Explicit interface member implementations

Explicit interface member implementations work with constructed interface types in essentially the same way as with simple interface types. As usual, an explicit interface member implementation shall be qualified by an interface-type indicating which interface is being implemented. This type can be a simple interface or a constructed interface [Example:

```csharp
interface IList<ElementType>
{
    ElementType[] GetElements();
}

interface IDictionary<KeyType,ElementType>
{
    ElementType this[KeyType key] { get; }
    void Add(KeyType key, ElementType value);
}

class List<ElementType>: IList<ElementType>, IDictionary<int,ElementType>
{
   ElementType[] IList<ElementType>.GetElements() {…}
    // Return the element at index
    ElementType IDictionary<int,ElementType>.this[int index] {…}
    // Add value at the index
    void IDictionary<int,ElementType>.Add(int index, ElementType value)
    {…}
}

end example]

25.4 Generic delegate declarations

[Note: A delegate declaration (§22.1), can optionally define type parameters and their associated constraints:

delegate-declaration:
    attributes_opt delegate-modifiers_opt delegate return-type identifier type-parameter-list_opt
                   ( formal-parameter-list_opt ) type-parameter-constraints-clauses_opt;

end note]

Generic delegate declarations follow the same rules as non-generic delegate declarations, except where noted below. Each type parameter in a generic delegate declaration defines a name in a special declaration space (§10.3) that is associated with that delegate declaration. The scope (§10.7) of a type parameter in a delegate declaration includes the return-type, formal-parameter-list, and type-parameter-constraints-clauses.

Like other generic type declarations, type arguments shall be given to create a constructed delegate type. The parameter types and return type of a constructed delegate type are created by substituting, for each type parameter in the delegate declaration, the corresponding type argument of the constructed delegate type. The resulting return type and parameter types are used in determining what methods are consistent (§22.1) with a constructed delegate type. [Example:

delegate bool Predicate<T>(T value);

class X
{
    static void Main()
    {
        Predicate<int> p1 =
            delegate(int i) {
                //…
            };
    }
}
Generics

Predicate<string> p2 =
    delegate(string s) {
        //...
    };

end example

25.5 Constructed types

A generic type declaration, by itself, denotes an unbound generic type that is used as a “blueprint” to form many different types, by way of applying type arguments. The type arguments are written within angle brackets (< and >) immediately following the name of the generic type declaration. A type that is named with at least one type argument is called a constructed type. A constructed type can be used in most places in the language in which a type name can appear. An unbound generic type can only be used within a typeof-expression (§14.5.11).

Constructed types can also be used in expressions as simple names (§14.5.2) or when accessing a member (§14.5.4).

When a namespace-or-type-name is evaluated, only generic types with the correct number of type parameters are considered. Thus, it is possible to use the same identifier to identify different types, as long as the types have different numbers of type parameters. This is useful when mixing generic and non-generic classes in the same program. [Example:

```csharp
namespace Widgets
{
    class Queue {…}
    class Queue<ElementType> {…}
}
namespace MyApplication
{
    using Widgets;
    class X
    {
        Queue q1;   // Non-generic Widgets.Queue
        Queue<int> q2;  // Generic Widgets.Queue
    }
}
```

end example]

The detailed rules for name lookup in the namespace-or-typename productions is described in §10.8. The resolution of ambiguities in these productions is described in §9.2.3.

A type-name might identify a constructed type even though it doesn’t specify type parameters directly. This can occur where a type is nested within a generic class declaration, and the instance type of the containing declaration is implicitly used for name lookup (§25.1.11). [Example:

```csharp
class Outer<T>
{
    public class Inner {…}
    public Inner i;    // Type of i is Outer<T>.Inner
}
```

end example]

[Note: In unsafe code, a constructed type shall not be used as an unmanaged-type (§25.2). end note]

25.5.1 Type arguments

Each argument in a type argument list is simply a type.

```
type-argument-list:
    < type-arguments >
```
Type arguments can be constructed types or type parameters. [Note: In unsafe code ($\S$27), a type-argument shall not be a pointer-type. end note] Each type argument shall satisfy any constraints on the corresponding type parameter ($\S$25.7.1).

25.5.2 Open and closed types

All types can be classified as open types or closed types. An open type is a type that involves type parameters. More specifically:

- A type parameter defines an open type.
- An array type is an open type if and only if its element type is an open type.
- A constructed type is an open type if and only if one or more of its type arguments is an open type. A constructed nested type is an open type if and only if one or more of its type arguments or the type arguments of its containing type(s) is an open type.

A closed type is a type that is not an open type.

At run-time, all of the code within a generic type declaration is executed in the context of a closed constructed type that was created by applying type arguments to the generic declaration. Each type parameter within the generic type is bound to a particular run-time type. The run-time processing of all statements and expressions always occurs with closed types, and open types occur only during compile-time processing.

Each closed constructed type has its own set of static variables, which are not shared with any other closed constructed types. Since an open type does not exist at run-time, there are no static variables associated with an open type. Two closed constructed types are the same type if they are constructed from the same unbound generic type, and their corresponding type arguments are the same type.

25.5.3 Base classes and interfaces of a constructed type

A constructed class type has a direct base class, just like a simple class type. If the generic class declaration does not specify a base class, the base class is object. If a base class is specified in the generic class declaration, the base class of the constructed type is obtained by substituting, for each type-parameter in the base class declaration, the corresponding type-argument of the constructed type. [Example: Given the generic class declarations

```csharp
class B<U,V> {…}
class G<T>: B<string,T[]> {…}
```

the base class of the constructed type `G<int>` would be `B<string,int[]>`. end example]

Similarly, constructed class, struct, and interface types have a set of explicit base interfaces. The explicit base interfaces are formed by taking the explicit base interface declarations on the generic type declaration, and substituting, for each type-parameter in the base interface declaration, the corresponding type-argument of the constructed type.

The set of all base classes and base interfaces for a type is formed, as usual, by recursively getting the base classes and interfaces of the immediate base classes and interfaces. [Example: Given the generic class declarations:

```csharp
class A {…}
class B<T>: A {…}
class C<T>: B<IComparable<T>> {…}
```
class D<T>: C<T[]> {...
the base classes of D<int> are C<int[]>, B<IComparable<int[]>>, A, and object. end example]

25.5.4 Members of a constructed type

The non-inherited members of a constructed type are obtained by substituting, for each type-parameter in the member declaration, the corresponding type-argument of the constructed type. The substitution process is based on the semantic meaning of type declarations, and is not simply textual substitution.

[Example: Given the generic class declaration

```csharp
class Gen<T,U>
{
    public T[,] a;
    public void G(int i, T t, Gen<U,T> gt) {...}
    public U Prop { get {...} set {...} }
    public int H(double d) {...}
}
```

the constructed type Gen<int[],IComparable<string>> has the following members:

```csharp
    public int[,][] a;
    public void G(int i, int[] t, Gen<IComparable<string>,int[]> gt) {...}
    public IComparable<string> Prop { get {...} set {...} }
    public int H(double d) {...}
```

The type of the member a in the generic class declaration Gen is “two-dimensional array of T”, so the type of the member a in the constructed type above is “two-dimensional array of one-dimensional array of int”, or int[,][]. end example]

The inherited members of a constructed type are obtained in a similar way. First, all the members of the immediate base class are determined. If the base class is itself a constructed type, this might involve a recursive application of the current rule. Then, each of the inherited members is transformed by substituting, for each type-parameter in the member declaration, the corresponding type-argument of the constructed type. [Example:

```csharp
class B<U>
{
    public U F(long index) {...}
}
class D<T>: B<T[]>
{
    public T G(string s) {...}
}
```

In the above example, the constructed type D<int> has a non-inherited member public int G(string s) obtained by substituting the type argument int for the type parameter T. D<int> also has an inherited member from the class declaration B. This inherited member is determined by first determining the members of the constructed type B<T[]> by substituting T[] for U, yielding public T[] F(long index). Then, the type argument int is substituted for the type parameter T, yielding the inherited member public int[] F(long index). end example]

25.5.5 Accessibility of a constructed type

A constructed type C<T₁, ..., Tₙ> is accessible when all of its components C, T₁, ..., Tₙ are accessible. More precisely, the accessibility domain for a constructed type is the intersection of the accessibility domain of the unbound generic type and the accessibility domains of the type arguments.
25.5.6 Conversions

Constructed types follow the same conversion rules (§13) as do non-generic types. When applying these rules, the base classes and interfaces of constructed types shall be determined as described in §25.5.3.

No special conversions exist between constructed reference types other than those described in §13. In particular, unlike array types, constructed reference types do not exhibit “co-variant” conversions. This means that a type List<B> has no conversion (either implicit or explicit) to List<A> even if B is derived from A. Likewise, no conversion exists from List<B> to List<object>.

[Note: The rationale for this is simple: if a conversion to List<A> is permitted, then apparently, one can store values of type A into the list. However, this would break the invariant that every object in a list of type List<B> is always a value of type B, or else unexpected failures can occur when assigning into collection classes. end note]

[Example: The behavior of conversions and runtime type checks is illustrated below:

class A {}
class B: A {...}
class Collection {...}
class List<T>: Collection {...}
class Test{
    void F() {
        List<A> listA = new List<A>();
        List<B> listB = new List<B>();
        Collection c1 = listA;    // Ok, List<A> is a Collection
        Collection c2 = listB;    // Ok, List<B> is a Collection
        List<A> a1 = listB;     // Error, no implicit conversion
        List<A> a2 = (List<A>)listB;   // Error, no explicit conversion
    }
}
end example]

25.5.7 Using alias directives

Using aliases can name a closed constructed type, but shall not name a generic type declaration without supplying type arguments. [Example:

namespace N1
{
    class A<T>
    {
        class B {}
    }
}
namespace N2
{
    using W = N1.A;       // Error, cannot name generic type
    using X = N1.A.B;     // Error, cannot name generic type
    using Y = N1.A<int>;  // Ok, can name closed constructed type
}
end example]

25.6 Generic methods

A generic method is a method whose declaration includes a type-parameter-list (§17.5 and §20.2.1). Generic methods can be declared inside class, struct, or interface declarations, which can themselves, be either generic or non-generic. If a generic method is declared inside a generic type declaration, the body of the
Generics

The method can refer to both the type parameters of the method, and the type parameters of the containing declaration.

The type-parameter-list and type-parameter-constraints-clauses of a generic method declaration have the same syntax and purpose as in a generic type declaration. The method’s type-parameters are in scope throughout the method-declaration, and can be used to form types throughout that scope in return-type, method-body, and type-parameter-constraints-clauses but not in attributes.

The name of a method type parameter cannot be the same as the name of an ordinary parameter in the same method.

[Example: The following example finds the first element in an array, if any, that satisfies the given test delegate. (Generic delegates are described in §25.4.)

```csharp
public delegate bool Test<T>(T item);
public class Finder
{
    public static T Find<T>(T[] items, Test<T> test)
    {
        foreach (T item in items)
        {
            if (test(item))
                return item;
        }
        throw new InvalidOperationException("Item not found");
    }
}
```

end example]

25.6.1 Generic method signatures

For the purposes of signature comparisons any type-parameter-constraints-clauses are ignored, as are the names of the method’s type-parameters, but the number of generic type parameters is relevant, as are the ordinal positions of type-parameters in left-to-right ordering (§10.6). [Example: The following example shows how method signatures are affected by this rule:

```csharp
class A {}
class B {}
interface IX
{
    T F1<T>(T[] a, int i);  // Error, both declarations have the same
    void F1<U>(U[] a, int i); // signature because return type and type
                              // parameter names are not significant
    void F2<T>(int x);      // Ok, the number of type parameters is
    void F2(int x);         // part of the signature
    void F3<T>(T t) where T: A; // Error, constraints are not
    void F3<T>(T t) where T: B; // considered in signatures
}
```

end example]

25.6.2 Virtual generic methods

Generic methods can be declared using the abstract, virtual, and override modifiers. The signature matching rules described in §10.6 are used when matching methods for overriding or interface implementation. When a generic method overrides a generic method declared in a base class, or is an explicit interface member implementation of a method in a base interface, the method shall not specify any type-parameter-constraints-clauses. In these cases, the type parameters of the method inherit constraints from the method being overridden or implemented. [Example:

```csharp
abstract class Base
{
    public abstract T F<T,U>(T t, U u) where U : T;
}
public abstract T G<T>(T t) where T: IComparable;
}

interface I
{
  bool M<T>(T a, T b) where T : class;
}

class Derived: Base, I
{
  public override X F<X,Y>(X x, Y y)  // Ok
  {
    // The implicit constraint Y : X is inherited
    // so y is implicitly convertible to type X.
    return y;
  }
  public override T G<T>(T t)  
  where T: IComparable  // Error – constraints not allowed
  {
  ...
  }
  bool I.M<U>(U a, U b)
  {
    // The implicit constraint U : class is inherited
    // so a and b can be compared using the reference type
    // equality operators.
    return a == b;
  }
}

The override of F is valid because type parameter names are permitted to differ. Within Derived.F, the type parameter Y implicitly has the constraint Y : X as inherited from Base.F. The override of G is invalid because overrides are not permitted to specify type parameter constraints. The explicit method implementation I.M in Derived implicitly inherits the U : class constraint from the interface method.

end example

When a generic method implicitly implements an interface method, the constraints given for each method type parameter shall be equivalent in both declarations (after any interface type parameters are replaced with the appropriate type arguments), where method type parameters are identified by ordinal positions, left to right. [Example:

interface I<A, B, C>
{
  void F<T>(T t) where T : A;
  void G<T>(T t) where T : B;
  void H<T>(T t) where T : C;
}

class Cls : I<object,Cls,string>
{
  public void F<T>(T t) {...} // Ok
  public void G<T>(T t) where T : Cls {...} // Ok
  public void H<T>(T t) where T : string {...} // Error
}

The method Cls.F<T> implicitly implements I<object,Cls,string>.F<T>. In this case, Cls.F<T> is not required (nor permitted) to specify the constraint T : object since object is an implicit constraint on all type parameters. The method Cls.G<T> implicitly implements I<object,Cls,string>.G<T> because the constraints match those in the interface, after the interface type parameters are replaced with the corresponding type arguments. The constraint for method Cls.H<T> is an error since sealed types (string in this case) cannot be used as constraints. Omitting the constraint would also be an error since constraints of implicit interface method implementations are required to match. Thus, it’s impossible to implicitly implement I<object,Cls,string>.H<T>. This interface method needs to be implemented using an explicit interface member implementation:
class Cls : I<object,Cls,string>
{
 ... 
 public void H<U>(U u) where U : class {...}
 void I<object,Cls,string>.H<T>(T t)
{
    string s = t; // Ok
    H<T>(t);
}
}

In this example, the explicit interface member implementation invokes a public method having strictly weaker constraints. Note that the assignment from t to s is valid since T inherits a constraint of T : string, even though this constraint is not expressible in source code. end example]

25.6.3 Calling generic methods

A generic method invocation can explicitly specify a type argument list, or it can omit the type argument list and rely on type inference to determine the type arguments. The exact compile-time processing of a method invocation, including a generic method invocation, is described in §14.5.5.1. When a generic method is invoked without a type argument list, type inference takes place as described in §25.6.4.

[Example: The following example shows how overload resolution occurs after type inference and after type arguments are substituted into the parameter list:

class Test
{
    static void F<T>(int x, T y) {
        Console.WriteLine("one");
    }

    static void F<T>(T x, long y) {
        Console.WriteLine("two");
    }

    static void Main() {
        F<int>(5, 324);       // Ok, prints "one"
        F<byte>(5, 324);      // Ok, prints "two"
        F<double>(5, 324);    // Error, ambiguous
        F(5, 324);            // Ok, prints "one"
        F(5, 324L);           // Error, ambiguous
    }
}

} end example]  

25.6.4 Inference of type arguments

When a generic method is called without specifying type arguments, a type inference process attempts to infer type arguments for the call. The presence of type inference allows a more convenient syntax to be used for calling a generic method, and allows the programmer to avoid specifying redundant type information. [Example: Given the method declaration:

class Chooser
{
    static Random rand = new Random();

    public static T Choose<T>(T first, T second) {
        return (rand.Next(2) == 0) ? first : second;
    }
}

it is possible to invoke the Choose method without explicitly specifying a type argument:

    int i = Chooser.Choose(5, 213);       // Calls Choose<int>
    string s = Chooser.Choose("foo", "bar"); // Calls Choose<string>
Type inference occurs as part of the compile-time processing of a method invocation (§14.5.5.1) and takes place before the overload resolution step of the invocation. When a particular method group is specified in a method invocation, and no type arguments are specified as part of the method invocation, type inference is applied to each generic method in the method group. If type inference succeeds, then the inferred type arguments are used to determine the types of arguments for subsequent overload resolution. If overload resolution chooses a generic method as the one to invoke, then the inferred type arguments are used as the runtime type arguments for the invocation. If type inference for a particular method fails, that method does not participate in overload resolution. The failure of type inference, in and of itself, does not cause a compile-time error. However, it often leads to a compile-time error when overload resolution then fails to find any applicable methods.

If the supplied number of arguments is different from the number of parameters in the method, then inference immediately fails. Otherwise, type inference first occurs independently for each regular argument that is supplied to the method. Assume this argument has type $A$, and the corresponding parameter has type $P$. Type inferences are produced by relating the types $A$ and $P$ according to the following steps:

- Nothing is inferred from the argument (but type inference succeeds) if any of the following are true:
  - $P$ does not involve any method type parameters.
  - The argument has the null type (§11.2.7).
  - The argument is an anonymous method.
  - The argument is a method group.

- If $P$ is an array type, and $A$ is an array type of the same rank, then replace $A$ and $P$, respectively, with the element types of $A$ and $P$, and repeat this step.

- If $P$ is an array type, and $A$ is an instantiation of $IList<>$, $ICollection<>$, or $IEnumerable<>$, then replace $A$ and $P$, respectively, with the element types of $A$ and $P$, and repeat this step.

- If $P$ is an array type, and $A$ is not an array type of the same rank, or an instantiation of $IList<>$, $ICollection<>$, or $IEnumerable<>$, then type inference fails for the generic method.

- If $P$ is a method type parameter, then type inference succeeds for this argument, and $A$ is the type inferred for that type parameter.

- Otherwise, $P$ shall be a constructed type. If, for each method type parameter $M_X$ that occurs in $P$, exactly one type $T_X$ can be determined such that replacing each $M_X$ with each $T_X$ produces a type to which $A$ is convertible by a standard implicit conversion, then inferencing succeeds for this argument, and each $T_X$ is the type inferred for each $M_X$. Method type parameter constraints, if any, are ignored for the purpose of type inference. If, for a given $M_X$, no $T_X$ exists, or more than one $T_X$ exists, then type inference fails for the generic method (a situation where more than one $T_X$ exists can only occur if $P$ is a generic interface type and $A$ implements multiple constructed versions of that interface).

If all of the method arguments are processed successfully by the above algorithm, then all inferences that were produced from the arguments are pooled. Type inference is said to have succeeded for the given generic method and argument list if both of the following are true:

- Each type parameter of the method had a type argument inferred for it (in short, the set of inferences is complete).
- For each type parameter, all of the inferences for that type parameter infer the same type argument (in short, the set of inferences is consistent).

If the generic method was declared with a parameter array (§17.5.1.4), then type inference is first performed against the method in its normal form. If type inference succeeds, and the resultant method is applicable, then the method is eligible for overload resolution in its normal form. Otherwise, type inference is performed against the method in its expanded form (§14.4.2.1).
25.6.5 Using a generic method with a delegate

An instance of a delegate can be created that refers to a generic method declaration. The exact compile-time processing of a delegate creation expression, including a delegate creation expression that refers to a generic method, is described in §14.5.10.3.

The type arguments used when invoking a generic method through a delegate are determined when the delegate is instantiated. The type arguments can be given explicitly via a type-argument-list, or determined by type inference (§25.6.4). If type inference is used, the parameter types of the delegate are used as argument types in the inference process. The return type of the delegate is not used for inference. [Example: The following example shows both ways of supplying a type argument to a delegate instantiation expression:

```csharp
delegate int D(string s, int i);
delegate int E();
class X{
    public static T F<T>(string s, T t) {...}
    public static T G<T>() {...}
    static void Main() {
        D d1 = new D(F<int>);  // Ok, type argument given explicitly
        D d2 = new D(F);    // Ok, int inferred as type argument
        E e1 = new E(G<int>);  // Ok, type argument given explicitly
        E e2 = new E(G);    // Error, cannot infer from return type
    }
}
```

] Whenever a generic method is used to create delegate instance, type arguments are given or inferred when the delegate instance is created, and a type-argument-list shall not be supplied when the delegate is invoked (§22.3).

25.6.6 No generic properties, events, indexers, operators, constructors, or finalizers

Properties, events, indexers, operators, constructors, and finalizers shall not themselves have type parameters (although they can occur in generic types, and use the type parameters from an enclosing type).

25.7 Constraints

Generic type and method declarations can optionally specify type parameter constraints by including a type-parameter-constraints-clauses in the declaration.

```
type-parameter-constraints-clauses:
type-parameter-constraints-clause
    type-parameter-constraints-clauses   type-parameter-constraints-clause

    type-parameter-constraints-clause:
        where type-parameter : type-parameter-constraints

type-parameter-constraints:
    primary-constraint
    secondary-constraints
    constructor-constraint
    primary-constraint , secondary-constraints
    primary-constraint , constructor-constraint
    secondary-constraints , constructor-constraint
    primary-constraint , secondary-constraints , constructor-constraint
```
primary-constraint:
  class-type
    class
    struct

secondary-constraints:
  interface-type
  type-parameter
  secondary-constraints, interface-type
  secondary-constraints, type-parameter

constructor-constraint:
  new ( )

Each type-parameter-constraints-clause consists of the token where, followed by the name of a type parameter, followed by a colon and the list of constraints for that type parameter. There shall be at most one where clause for each type parameter, and the where clauses can be listed in any order. The where token is not a keyword.

The list of constraints given in a where clause can include any of the following components, in this order: a single primary constraint, one or more secondary constraints, and the constructor constraint, new().

A primary constraint can be a class type or the reference type constraint class or the value type constraint struct. A secondary constraint can be a type-parameter or interface-type.

The reference type constraint specifies that a type argument used for the type parameter must be a reference type (§25.7.1). Any class type, interface type, delegate type, array type, or type parameter known to be a reference type (as defined below) satisfies this constraint.

The value type constraint specifies that a type argument used for the type parameter must be a value type (§25.7.1). Any non-nullable struct type, enum type, or type parameter having the value type constraint satisfies this constraint. A type parameter having the value type constraint shall not also have the constructor-constraint. The System.Nullable<T> type specifies the non-nullable value type constraint for T. Thus, recursively constructed types of the forms T?? and Nullable<Nullable<T>> are prohibited.

Pointer types are never allowed to be type arguments so they are not considered to satisfy the reference type or value type constraints.

If a constraint is a class type, an interface type, or a type parameter, that type specifies a minimal “base type” that every type argument used for that type parameter shall support. Whenever a constructed type or generic method is used, the type argument is checked against the constraints on the type parameter at compile-time. The type argument supplied shall derive from or implement all of the constraints given for that type parameter.

A class-type constraint shall satisfy the following rules:
  • The type shall be a class type.
  • The type shall not be sealed.
  • The type shall not be one of the following types: System.Array, System.Delegate, System.Enum, or System.ValueType.
  • The type shall not be object. [Note: Since all types derive from object, such a constraint would have no effect if it were permitted. end note]
  • At most one constraint for a given type parameter can be a class type.

A type specified as an interface-type constraint shall satisfy the following rules:
  • The type shall be an interface type.
  • A type shall not be specified more than once in a given where clause.
In either case, the constraint can involve any of the type parameters of the associated type or method declaration as part of a constructed type, and can involve the type being declared.

Any class or interface type specified as a type parameter constraint shall be at least as accessible (§10.5.4) as the generic type or method being declared.

A type specified as a type-parameter constraint shall satisfy the following rules:

- The type shall be a type parameter.
- A type shall not be specified more than once in a given where clause.

In addition, there shall be no cycles in the dependency graph of type parameters, where dependency is a transitive relation defined by:

- If a type parameter $T$ is used as a constraint for type parameter $S$ then $S$ depends on $T$.
- If a type parameter $S$ depends on a type parameter $T$ and $T$ depends on a type parameter $U$ then $S$ depends on $U$.

Given this relation, it is a compile-time error for a type parameter to depend on itself (directly or indirectly).

Any constraints must be consistent among dependent type parameters. If type parameter $S$ depends on type parameter $T$ then:

- $T$ must not have the value type constraint. Otherwise, $T$ is effectively sealed so $S$ would be forced to be the same type as $T$, eliminating the need for two type parameters.
- If $S$ has the value type constraint then $T$ must not have a class-type constraint.
- If $S$ has a class-type constraint $A$ and $T$ has a class-type constraint $B$ then there must be an identity conversion or implicit reference conversion from $A$ to $B$ or an implicit reference conversion from $B$ to $A$.
- If $S$ also depends on type parameter $U$ and $U$ has a class-type constraint $A$ and $T$ has a class-type constraint $B$ then there must be an identity conversion or implicit reference conversion from $A$ to $B$ or an implicit reference conversion from $B$ to $A$.

It is valid for $S$ to have the value type constraint and $T$ to have the reference type constraint. Effectively this limits $T$ to the types System.Object, System.ValueType, System.Enum and any interface type.

If the where clause for a type parameter includes a constructor constraint (which has the form new()), it is possible to use the new operator to create instances of the type (§14.5.10.1). Any type argument used for a type parameter with a constructor constraint shall have a public parameterless constructor (this includes all value types) or be a type parameter having the value type constraint or constructor constraint (see §25.7.1 for details).

[Example: The following are examples of constraints:

```csharp
interface IPrintable
{
    void Print();
}
interface IComparable<T>
{
    int CompareTo(T value);
}
interface IKeyProvider<T>
{
    T GetKey();
}

class Printer<T> where T: IPrintable {...}
class SortedList<T> where T: IComparable<T> {...}
```
class Dictionary<K, V>
    where K: IComparable<K>
    where V: IPrintable, IKeyProvider<K>, new()
{
    }

The following example is in error because it causes a circularity in the dependency graph of the type parameters:

class Circular<S, T>
    where S: T
    where T: S       // Error – circularity in dependency graph
{
...
}

The following examples illustrate additional invalid situations:

class Sealed<S, T>
    where S: T
    where T: struct       // Error – T is sealed
{
...
}
class A {...}
class B {...}
class Incompat<S, T>
    where S: A, T
    where T: B       // Error – incompatible class-type constraints
{
...
}
class StructWithClass<S, T, U>
    where S: struct, T
    where T: U
    where U: A       // Error – A incompatible with struct
{
...
}

end example

The effective base class of a type parameter T is defined as follows:

- If T has no primary constraints or type parameter constraints, its effective base class is object.
- If T has the value type constraint, its effective base class is System.ValueType.
- If T has a class-type constraint C but no type-parameter constraints, its effective base class is C.
- If T has no class-type constraint but has one or more type-parameter constraints, its effective base class is the most encompassed type (§13.4.2) in the set of effective base classes of its type-parameter constraints. The consistency rules ensure that such a most encompassed type exists.
- If T has both a class-type constraint and one or more type-parameter constraints, its effective base class is the most encompassed type (§13.4.2) in the set consisting of the class-type constraint of T and the effective base classes of its type-parameter constraints. The consistency rules ensure that such a most encompassed type exists.

The effective interface set of a type parameter T is defined as follows:

- If T has no secondary-constraints, its effective interface set is empty.
- If T has interface-type constraints but no type-parameter constraints, its effective interface set is its set of interface-type constraints.
- If T has no interface-type constraints but has type-parameter constraints, its effective interface set is the union of the effective interface sets of its type-parameter constraints.
- If T has both interface-type constraints and type-parameter constraints, its effective interface set is the union of its set of interface-type constraints and the effective interface sets of its type-parameter constraints.
A type parameter is known to be a reference type if it has the reference type constraint or its effective base class is not object or System.ValueType.

Values of a constrained type parameter type can be used to access the instance members implied by the constraints. [Example: In the following code]

```csharp
interface I Printable
{
    void Print();
}

class Printer<T> where T: I Printable
{
    void PrintOne(T x) {
        x.Print();
    }
}
```

the methods of IPrintable can be invoked directly on x because T is constrained to always implement IPrintable. end example]

Two generic partial type declarations (in the same program) contribute to the same unbound generic type if they have the same fully qualified name (which includes the number of type parameters) (§10.3). Two such partial type declarations shall specify the same name for each type parameter, in order.

When a partial generic type declaration includes constraints, the constraints shall agree with all other parts that include constraints. Specifically, each part that includes constraints shall have constraints for the same set of type parameters, and for each type parameter, the sets of primary, secondary, and constructor constraints shall be equivalent. Two sets of constraints are equivalent if they contain the same members. If no part of a partial generic type specifies type parameter constraints, the type parameters are considered unconstrained. [Example:

```csharp
partial class Map<K,V>
    where K: IComparable<K>
    where V: IKeyProvider<K>, new()
{
    ...
}

partial class Map<K,V>
    where V: IKeyProvider<K>, new()
    where K: IComparable<K>
{
    ...
}

partial class Map<K,V>
{
    ...
}
```

is correct because those parts that include constraints (the first two) effectively specify the same set of primary, secondary, and constructor constraints for the same set of type parameters, respectively. end example]

### 25.7.1 Satisfying constraints

Whenever a constructed type or generic method is referenced, the supplied type arguments are checked against the type parameter constraints declared on the generic type or method. For each where clause, the type argument A that corresponds to the named type parameter is checked against each constraint as follows:

- If the constraint is a class type, an interface type, or a type parameter, let C represent that constraint with the supplied type arguments substituted for any type parameters that appear in the constraint. To satisfy the constraint, it shall be the case that type A is convertible to type C by one of the following:
  - An identity conversion (§13.1.1)
An implicit reference conversion (§13.1.4)

A boxing conversion (§13.1.5)

An implicit conversion from a type parameter $A$ to $C$ (§25.7.4).

- If the constraint is the reference type constraint, the type $A$ must satisfy one of the following:
  - $A$ is an interface type, class type, delegate type or array type. [Note: Note that System.ValueType and System.Enum are reference types so satisfy this constraint. end note]
  - $A$ is a type parameter that is known to be a reference type (§25.7).

- If the constraint is the value type constraint, the type $A$ must satisfy one of the following:
  - $A$ is a non-nullable struct type or enum type. [Note: Note that System.ValueType and System.Enum are reference types so do not satisfy this constraint. end note]
  - $A$ is a type parameter having the value type constraint (§25.7).

- If the constraint is the constructor constraint new(), the type argument $A$ shall not be abstract and shall have a public parameterless constructor. This is satisfied if one of the following is true:
  - $A$ is a value type, since all value types have a public default constructor (§11.1.2).
  - $A$ is a type parameter having the value type constraint (§25.7).
  - $A$ is a class that is not abstract, $A$ contains an explicitly declared public constructor with no parameters.
  - $A$ is not abstract and has a default constructor (§17.10.4).

A compile-time error occurs if one or more of a type parameter’s constraints are not satisfied by the given type arguments.

Since type parameters are not inherited, constraints are never inherited either. [Example: In the code below, $D$ needs to specify the constraint on its type parameter $T$, so that $T$ satisfies the constraint imposed by the base class $B<T>$. In contrast, class $E$ need not specify a constraint, because $List<T>$ implements IEnumerable for any $T$.

```csharp
class B<T> where T: IEnumerable {…}
class D<T>: B<T> where T: IEnumerable {…}
class E<T>: B<List<T>> {…}
```

end example]

### 25.7.2 Member lookup on type parameters

The results of member lookup in a type given by a type parameter $T$ depends on the constraints, if any, specified for $T$. If $T$ has no class-type, interface-type or type-parameter constraints, then member lookup on $T$ returns the same set of members as member lookup on object. Otherwise, the first stage of member lookup (§14.3) considers all the members in the effective base class of $T$ and all the members in each interface in the effective interface set of $T$. After performing the first stage of member lookup for each of theses types, the results are combined, and then hidden members are removed from the combined results.

Before the advent of generics, member lookup always returned either a set of members declared solely in classes, or a set of members declared solely in interfaces and possibly the type object. Member lookup on type parameters changes this somewhat. When a type parameter has both an effective base class other than object and a non-empty effective interface set, member lookup can return a set of members, some of which were declared in a class, and others of which were declared in an interface. The following additional rules handle this case.

- As specified in §14.3, during member lookup, members declared in a class other than object hide members declared in interfaces.
During overload resolution of methods (§14.5.5.1) and indexers (§14.5.6.2), if any applicable member was declared in a class other than `object`, all members declared in an interface are removed from the set of considered members.

These rules only have effect when doing binding on a type parameter with both an effective base class other than `object` and a non-empty effective interface set. [Note: Informally, members defined in a class type constraint are preferred over members in an interface constraint. end note]

### 25.7.3 Type parameters and boxing

When a struct type overrides a virtual method inherited from `System.Object` (such as `Equals`, `GetHashCode`, or `ToString`), invocation of the virtual method through an instance of the struct type doesn’t cause boxing to occur. This is true even when the struct is used as a type parameter and the invocation occurs through an instance of the type parameter type. [Example:

```csharp
using System;
struct Counter
{
    int value;
    public override string ToString() {
        value++;
        return value.ToString();
    }
}
class Program
{
    static void Test<T>() where T: new() {
        T x = new T();
        Console.WriteLine(x.ToString());
        Console.WriteLine(x.ToString());
        Console.WriteLine(x.ToString());
    }
    static void Main() {
        Test<Counter>();
    }
}
```

The output of the program is:

1
2
3

Although it is bad style for `ToString` to have side effects, the example demonstrates that no boxing occurred for the three invocations of `x.ToString()`. end example]

Similarly, boxing never implicitly occurs when accessing a member on a constrained type parameter. [Example: Suppose an interface `ICounter` contains a method `Increment`, which can be used to modify a value. If `ICounter` is used as a constraint, the implementation of the `Increment` method is called with a reference to the variable that `Increment` was called on, never a boxed copy. This behavior is different from the non-generic case. When making a call to an interface implementation on a struct type the argument is always boxed.

```csharp
using System;
interface ICounter
{
    void Increment();
}
struct Counter: ICounter
{
    int value;
}
```
public override string ToString() {
    return value.ToString();
}
void ICounter.Increment() {
    value++;
}

class Program {
    static void Test<T>() where T: ICounter, new() {
        T x = new T();
        Console.WriteLine(x);
        x.Increment(); // Modify x
        Console.WriteLine(x);
        ((ICounter)x).Increment(); // Modify boxed copy of x
        Console.WriteLine(x);
    }
    static void Main() {
        Test<Counter>();
    }
}

The first call to Increment modifies the value in the variable x. This is not equivalent to the second call to Increment, which modifies the value in a boxed copy of x. Thus, the output of the program is:
0
1
1

25.7.4 Conversions involving type parameters

The conversions that are allowed on a type parameter T depend on the constraints specified for T and are detailed in §13.

The conversion rules do not permit a direct explicit conversion from an unconstrained type parameter to an arbitrary non-interface type, which might be surprising. The reason for this rule is to prevent confusion and make the semantics of such conversions clear. [Example: Consider the following declaration:

class X<T>
{
    public static long F(T t) {
        return (long)t; // Error, explicit conversion not permitted
    }
}

If the direct explicit conversion of t to long were permitted, one might easily expect that X<int>.F(7) would return 7L. However, it would not, because the standard numeric conversions are only considered when the types are known to be numeric at compile time. In order to make the semantics clear, the above example should be written:

class X<T>
{
    public static long F(T t) {
        return (long)(object)t; // OK, conversions permitted
    }
}

This code will now compile but executing X<int>.F(7) would then throw an exception at runtime, since a boxed int cannot be converted directly to a long.
end example]
26. Iterators

An *iterator* is a means of implementing a function member whose return type is an enumerator interface or enumerable interface. The function member returns the ordered sequence of values as yielded by the iterator.

*[Example:]* The following `Stack<T>` class implements its `GetEnumerator` method using an iterator. The iterator enumerates the elements of the stack in top to bottom order.

```csharp
using System.Collections.Generic;
public class Stack<T> : IEnumerable<T>
{
    T[] items;
    int count;
    public void Push(T data) {...}
    public T Pop() {...}
    public IEnumerator<T> GetEnumerator() {
        for (int i = count - 1; i >= 0; --i) {
            yield return items[i];
        }
    }
}
```

Iterators are implemented using `yield` statements, which can only be used in methods whose return type is an enumerator interface. The presence of the `GetEnumerator` method makes `Stack<T>` an enumerable type, allowing instances of `Stack<T>` to be used in a `foreach` statement. The following example pushes the values 0 through 9 onto an integer stack and then uses a `foreach` loop to display the values in top to bottom order.

```csharp
using System;
class Test
{
    static void Main()
    {
        Stack<int> s = new Stack<int>();
        for (int i = 0; i < 10; i++) s.Push(i);
        foreach (int i in s) Console.Write("{0} ", i);
        Console.WriteLine();
    }
}
```

The output of the example is:

```
9 8 7 6 5 4 3 2 1 0
```

**26.1 Iterator blocks**

An *iterator block* is a *block* (§15.2) that yields an ordered sequence of values. An iterator block is distinguished from a normal statement block by the presence of one or more `yield` statements (§15.14).

- The `yield return` statement produces the next value of the iteration.
- The `yield break` statement indicates that the iteration is complete.

An iterator block can be used as a *method-body* (§17.5), *operator-body* (§17.9), or *accessor-body* (§17.6.2) as long as the return type of the corresponding function member is one of the enumerator interfaces (§26.1.1) or one of the enumerable interfaces (§26.1.2).
Iterator blocks are not a distinct element in the C# grammar. They are restricted in several ways and have a major effect on the semantics of a function member declaration; however, grammatically, they are just blocks.

When a function member is implemented using an iterator block, it is a compile-time error for the formal parameter list of the function member to specify any ref or out parameters.

It is a compile-time error for a return statement to appear in an iterator block (but yield return statements are permitted).

It is a compile-time error for an iterator block to contain an unsafe context (§27.1). An iterator block always defines a safe context, even when its declaration is nested in an unsafe context.

26.1.1 Enumerator interfaces

The enumerator interfaces are the non-generic interface System.Collections.IEnumerator and all instantiations of the generic interface System.Collections.Generic.IEnumerable<T>. For the sake of brevity, these interfaces are referenced in this specification as IEnumerator and IEnumerator<T>, respectively.

26.1.2 Enumerable interfaces

The enumerable interfaces are the non-generic interface System.Collections.IEnumerable and all instantiations of the generic interface System.Collections.Generic.IEnumerable<T>. For the sake of brevity, these interfaces are referenced in this specification as IEnumerable and IEnumerable<T>, respectively.

26.1.3 Yield type

An iterator block produces a sequence of values, all of the same type. This type is called the yield type of the iterator block.

- The yield type of an iterator block used to implement a function member that returns IEnumerator or IEnumerable is object.
- The yield type of an iterator block used to implement a function member that returns IEnumerator<T> or IEnumerable<T> is T.

26.1.4 This access

Within an iterator block of an instance member of a class, the expression this is classified as a value. The type of the value is the class within which the usage occurs, and the value is a reference to the object for which the member was invoked.

Within an iterator block of an instance member of a struct, the expression this is classified as a variable. The type of the variable is the struct within which the usage occurs. The variable represents a copy of the struct for which the member was invoked. The this variable in an iterator block of an instance member of a struct behaves exactly the same as a value parameter of the struct type. [Note: This is different than in a non-iterator function member body. end note]

26.2 Enumerator objects

When a function member returning an enumerator interface type is implemented using an iterator block, invoking the function member does not immediately execute the code in the iterator block. Instead, an enumerator object is created and returned. This object encapsulates the code specified in the iterator block, and execution of the code in the iterator block occurs when the enumerator object’s MoveNext method is invoked. An enumerator object has the following characteristics:

- It implements IEnumerator and IEnumerator<T>, where T is the yield type of the iterator block.
- It implements System.IDisposable.
• It is initialized with a copy of the argument values (if any) and instance value passed to the function member.

• It has four potential states, *before*, *running*, *suspended*, and *after*, and is initially in the *before* state.

An enumerator object is typically an instance of a compiler-generated enumerator class that encapsulates the code in the iterator block and implements the enumerator interfaces, but other methods of implementation are possible. If an enumerator type is generated by the compiler, that class shall be nested, directly or indirectly, in the type containing the function member, it shall have private accessibility, and it shall have a name reserved for compiler use (§9.4.2).

An enumerator object can implement more interfaces than those specified above.

The following subclauses describe the exact behavior of the `MoveNext`, `Current`, and `Dispose` members of the `IEnumerable` and `IEnumerable<T>` interface implementations provided by an enumerator object.

Enumerators do not support the `IEnumerator.Reset` method. Invoking this method causes a `System.NotSupportedException` to be thrown.

26.2.1 The `MoveNext` method

The `MoveNext` method of an enumerator object encapsulates the code of an iterator block. Invoking the `MoveNext` method executes code in the iterator block and sets the `Current` property of the enumerator object as appropriate. The precise action performed by `MoveNext` depends on the state of the enumerator object when `MoveNext` is invoked:

• If the state of the enumerator object is *before*, invoking `MoveNext`:
  o Changes the state to *running*.
  o Initializes the parameters (including `this`) of the iterator block to the argument values and instance value saved when the enumerator object was initialized.
  o Executes the iterator block from the beginning until execution is interrupted (as described below).

• If the state of the enumerator object is *running*, the result of invoking `MoveNext` is unspecified.

• If the state of the enumerator object is *suspended*, invoking `MoveNext`:
  o Changes the state to *running*.
  o Restores the values of all local variables and parameters (including `this`) to the values saved when execution of the iterator block was last suspended. (Note that the contents of any objects referenced by these variables might have changed since the previous call to `MoveNext`.)
  o Resumes execution of the iterator block immediately following the `yield return` statement that caused the suspension of execution, and continues until execution is interrupted (as described below).

• If the state of the enumerator object is *after*, invoking `MoveNext` returns `false`.

When `MoveNext` executes the iterator block, execution can be interrupted in four ways: By a `yield return` statement, by a `yield break` statement, by encountering the end of the iterator block, or by an exception being thrown and propagated out of the iterator block.

• When a `yield return` statement is encountered (§15.14):
  o The expression given in the statement is evaluated, implicitly converted to the yield type, and assigned to the `Current` property of the enumerator object.
  o Execution of the iterator body is suspended. The values of all local variables and parameters (including `this`) are saved, as is the location of this `yield return` statement. If the `yield return` statement is within one or more `try` blocks, the associated `finally` blocks are not executed at this time.
The state of the enumerator object is changed to `suspended`.

The `MoveNext` method returns `true` to its caller, indicating that the iteration successfully advanced to the next value.

- When a `yield break` statement is encountered (§15.14):
  - If the `yield break` statement is within one or more `try` blocks, the associated `finally` blocks are executed.
  - The state of the enumerator object is changed to `after`.
  - The `MoveNext` method returns `false` to its caller, indicating that the iteration is complete.

- When the end of the iterator body is encountered:
  - The state of the enumerator object is changed to `after`.
  - The `MoveNext` method returns `false` to its caller, indicating that the iteration is complete.

- When an exception is thrown and propagated out of the iterator block:
  - Appropriate `finally` blocks in the iterator body will have been executed by the exception propagation.
  - The state of the enumerator object is changed to `after`.
  - The exception propagation continues to the caller of the `MoveNext` method.

### 26.2.2 The Current property

An enumerator object’s `Current` property is affected by `yield return` statements in the iterator block.

When an enumerator object is in the `suspended` state, the value of `Current` is the value set by the previous call to `MoveNext`. When an enumerator object is in the `before`, `running`, or `after` states, the result of accessing `Current` is unspecified.

For an iterator block with a yield type other than `object`, the result of accessing `Current` through the enumerator object’s `IEnumerable` implementation corresponds to accessing `Current` through the enumerator object’s `IEnumerator<T>` implementation and casting the result to `object`.

### 26.2.3 The Dispose method

The `Dispose` method is used to clean up the iteration by bringing the enumerator object to the `after` state.

- If the state of the enumerator object is `before`, invoking `Dispose` changes the state to `after`.
- If the state of the enumerator object is `running`, the result of invoking `Dispose` is unspecified.
- If the state of the enumerator object is `suspended`, invoking `Dispose`:
  - Changes the state to `running`.
  - Executes any `finally` blocks as if the last executed `yield return` statement were a `yield break` statement. If this causes an exception to be thrown and propagated out of the iterator body, the state of the enumerator object is set to `after` and the exception is propagated to the caller of the `Dispose` method.
  - Changes the state to `after`.
- If the state of the enumerator object is `after`, invoking `Dispose` has no affect.

### 26.3 Enumerable objects

When a function member returning an enumerable interface type is implemented using an iterator block, invoking the function member does not immediately execute the code in the iterator block. Instead, an `enumerator object` is created and returned. The enumerable object’s `GetEnumerator` method returns an
enumerator object that encapsulates the code specified in the iterator block, and execution of the code in the iterator block occurs when the enumerator object’s MoveNext method is invoked. An enumerable object has the following characteristics:

- It implements IEnumerable and IEnumerable<T>, where T is the yield type of the iterator block.
- It is initialized with a copy of the argument values (if any) and instance value passed to the function member.

An enumerable object is typically an instance of a compiler-generated enumerable class that encapsulates the code in the iterator block and implements the enumerable interfaces, but other methods of implementation are possible. If an enumerable class is generated by the compiler, that class shall be nested, directly or indirectly, in the class containing the function member, it shall have private accessibility, and it shall have a name reserved for compiler use (§9.4.2).

[Note: An enumerable object can implement more interfaces than those specified above. In particular, an enumerable object can also implement IEnumerator and IEnumerator<T>, enabling it to serve as both an enumerable and an enumerator. In that type of implementation, the first time an enumerable object’s GetEnumerator method is invoked, the enumerable object itself is returned. Subsequent invocations of the enumerable object’s GetEnumerator, if any, return a copy of the enumerable object. Thus, each returned enumerator has its own state, and changes in one enumerator will not affect another. end note]

26.3.1 The GetEnumerator method

An enumerable object provides an implementation of the GetEnumerator methods of the IEnumerable and IEnumerable<T> interfaces. The two GetEnumerator methods share a common implementation that acquires and returns an available enumerator object. The enumerator object is initialized with the argument values and instance value saved when the enumerable object was initialized, but otherwise the enumerator object functions as described in §26.2.

26.4 Implementation example

[Note: This section describes a possible implementation of iterators in terms of standard C# constructs. The implementation described here is by no means a mandated implementation or the only one possible.

The following Stack<T> class implements its GetEnumerator method using an iterator. The iterator enumerates the elements of the stack in top to bottom order.

```csharp
using System;
using System.Collections;
using System.Collections.Generic;

class Stack<T>: IEnumerable<T>
{
    T[] items;
    int count;

    public void Push(T item)
    {
        if (items == null)
        {
            items = new T[4];
        }
        else if (items.Length == count)
        {
            T[] newItems = new T[count * 2];
            Array.Copy(items, 0, newItems, 0, count);
            items = newItems;
        }
        items[count++] = item;
    }

    public T Pop()
    {
        T result = items[--count];
        items[count] = default(T);
        return result;
    }
}
```
The `GetEnumerator` method can be translated into an instantiation of a compiler-generated enumerator class that encapsulates the code in the iterator block, as shown in the following.

```csharp
class Stack<T>: IEnumerable<T>
{
    ...
    public IEnumerator<T> GetEnumerator() {
        return new __Enumerator1(this);
    }
    class __Enumerator1: IEnumerator<T>, IEnumerator
    {
        int __state;
        T __current;
        Stack<T> __this;
        int i;
        public __Enumerator1(Stack<T> __this) {
            this.__this = __this;
        }
        public T Current {
            get { return __current; }
        }
        object IEnumerator.Current {
            get { return __current; }
        }
        public bool MoveNext() {
            switch (__state) {
                case 1: goto __state1;
                case 2: goto __state2;
            }
            i = __this.count - 1;
            __loop:
            if (i < 0) goto __state2;
            __current = __this.items[i];
            __state = 1;
            return true;
            __state1:
            --i;
            goto __loop;
            __state2:
            __state = 2;
            return false;
        }
        public void Dispose() {
            __state = 2;
        }
        void IEnumerator.Reset() {
            throw new NotSupportedException();
        }
    }
}
```

In the preceding translation, the code in the iterator block is turned into a state machine and placed in the `MoveNext` method of the enumerator class. Furthermore, the local variable `i` is turned into a field in the enumerator object so it can continue to exist across invocations of `MoveNext`.

The following example prints a simple multiplication table of the integers 1 through 10. The `FromTo` method in the example returns an enumerable object and is implemented using an iterator.

```csharp
using System;
using System.Collections.Generic;

public IEnumerator<T> GetEnumerator() {
    for (int i = count - 1; i >= 0; --i) yield return items[i];
}
```

The `GetEnumerator` method can be translated into an instantiation of a compiler-generated enumerator class that encapsulates the code in the iterator block, as shown in the following.

```csharp
class Stack<T>: IEnumerable<T>
{
    ...
    public IEnumerator<T> GetEnumerator() {
        return new __Enumerator1(this);
    }
    class __Enumerator1: IEnumerator<T>, IEnumerator
    {
        int __state;
        T __current;
        Stack<T> __this;
        int i;
        public __Enumerator1(Stack<T> __this) {
            this.__this = __this;
        }
        public T Current {
            get { return __current; }
        }
        object IEnumerator.Current {
            get { return __current; }
        }
        public bool MoveNext() {
            switch (__state) {
                case 1: goto __state1;
                case 2: goto __state2;
            }
            i = __this.count - 1;
            __loop:
            if (i < 0) goto __state2;
            __current = __this.items[i];
            __state = 1;
            return true;
            __state1:
            --i;
            goto __loop;
            __state2:
            __state = 2;
            return false;
        }
        public void Dispose() {
            __state = 2;
        }
        void IEnumerator.Reset() {
            throw new NotSupportedException();
        }
    }
}
```

The following example prints a simple multiplication table of the integers 1 through 10. The `FromTo` method in the example returns an enumerable object and is implemented using an iterator.

```csharp
using System;
using System.Collections.Generic;

public IEnumerator<T> GetEnumerator() {
    for (int i = count - 1; i >= 0; --i) yield return items[i];
}
```

The `GetEnumerator` method can be translated into an instantiation of a compiler-generated enumerator class that encapsulates the code in the iterator block, as shown in the following.

```csharp
class Stack<T>: IEnumerable<T>
{
    ...
    public IEnumerator<T> GetEnumerator() {
        return new __Enumerator1(this);
    }
    class __Enumerator1: IEnumerator<T>, IEnumerator
    {
        int __state;
        T __current;
        Stack<T> __this;
        int i;
        public __Enumerator1(Stack<T> __this) {
            this.__this = __this;
        }
        public T Current {
            get { return __current; }
        }
        object IEnumerator.Current {
            get { return __current; }
        }
        public bool MoveNext() {
            switch (__state) {
                case 1: goto __state1;
                case 2: goto __state2;
            }
            i = __this.count - 1;
            __loop:
            if (i < 0) goto __state2;
            __current = __this.items[i];
            __state = 1;
            return true;
            __state1:
            --i;
            goto __loop;
            __state2:
            __state = 2;
            return false;
        }
        public void Dispose() {
            __state = 2;
        }
        void IEnumerator.Reset() {
            throw new NotSupportedException();
        }
    }
}
```
class Test
{
    static IEnumerable<int> FromTo(int from, int to) {
        while (from <= to) yield return from++;
    }
    static void Main() {
        IEnumerable<int> e = FromTo(1, 10);
        foreach (int x in e) {
            foreach (int y in e) {
                Console.Write("{0,3}" , x * y);
            }
            Console.WriteLine();
        }
    }
}

The FromTo method can be translated into an instantiation of a compiler-generated enumerable class that encapsulates the code in the iterator block, as shown in the following.

using System;
using System.Threading;
using System.Collections;
using System.Collections.Generic;

class Test
{
    ... 
    static IEnumerable<int> FromTo(int from, int to) {
        return new __Enumerable1(from, to);
    }
    class __Enumerable1:
        IEnumerable<int>, IEnumerable,
        IEnumerator<int>, IEnumerator
    {
        int __state;
        int __current;
        int __from;
        int from;
        int to;
        int i;
        public __Enumerable1(int __from, int to) {
            this.__from = __from;
            this.to = to;
        }
        public IEnumerator<int> GetEnumerator() {
            __Enumerable1 result = this;
            if (Interlocked.CompareExchange(ref __state, 1, 0) != 0) {
                result = new __Enumerable1(1, to);
                result.__state = 1;
            }
            result.from = result.__from;
            return result;
        }
        IEnumerator IEnumerable.GetEnumerator() {
            return (IEnumerator)GetEnumerator();
        }
        public int Current {
            get { return __current; }
        }
        object IEnumerator.Current {
            get { return __current; }
        }
    }
}
The enumerable class implements both the enumerable interfaces and the enumerator interfaces, enabling it to serve as both an enumerable and an enumerator. The first time the GetEnumerator method is invoked, the enumerable object itself is returned. Subsequent invocations of the enumerable object’s GetEnumerator, if any, return a copy of the enumerable object. Thus, each returned enumerator has its own state and changes in one enumerator will not affect another. The Interlocked.CompareExchange method is used to ensure thread-safe operation.

The from and to parameters are turned into fields in the enumerable class. Because from is modified in the iterator block, an additional __from field is introduced to hold the initial value given to from in each enumerator.

The MoveNext method throws an InvalidOperationException if it is called when __state is 0. This protects against use of the enumerable object as an enumerator object without first calling GetEnumerator.

The following example shows a simple tree class. The Tree<T> class implements its GetEnumerator method using an iterator. The iterator enumerates the elements of the tree in infix order.

```csharp
using System;
using System.Collections.Generic;

class Tree<T>: IEnumerable<T>
{
    T value;
    Tree<T> left;
    Tree<T> right;
    public Tree(T value, Tree<T> left, Tree<T> right) {
        this.value = value;
        this.left = left;
        this.right = right;
    }
    public IEnumerator<T> GetEnumerator() {
        if (left != null) foreach (T x in left) yield return x;
        yield return value;
        if (right != null) foreach (T x in right) yield return x;
    }
}
```
26 Iterators
class Program
{
static Tree<T> MakeTree<T>(T[] items, int left, int right) {
if (left > right) return null;
int i = (left + right) / 2;
return new Tree<T>(items[i],
MakeTree(items, left, i - 1),
MakeTree(items, i + 1, right));
}
static Tree<T> MakeTree<T>(params T[] items) {
return MakeTree(items, 0, items.Length - 1);
}
// The output of the program is:
// 1 2 3 4 5 6 7 8 9
// Mon Tue Wed Thu Fri Sat Sun
//
static void Main() {
Tree<int> ints = MakeTree(1, 2, 3, 4, 5, 6, 7, 8, 9);
foreach (int i in ints) Console.Write("{0} ", i);
Console.WriteLine();
Tree<string> strings = MakeTree("Mon", "Tue", "Wed", "Thu",
"Fri", "Sat", "Sun");
foreach (string s in strings) Console.Write("{0} ", s);
Console.WriteLine();
}
}

The GetEnumerator method can be translated into an instantiation of a compiler-generated enumerator
class that encapsulates the code in the iterator block, as shown in the following.
class Tree<T>: IEnumerable<T>
{
…
public IEnumerator<T> GetEnumerator() {
return new __Enumerator1(this);
}
sealed class __Enumerator1 : IEnumerator<T>, IEnumerator
{
Node<T> __this;
IEnumerator<T> __left, __right;
int __state;
T __current;
public __Enumerator1(Node<T> __this) { this.__this = __this; }
public T Current { get { return __current; } }
public bool MoveNext() {
try {
switch (__state) {
case 0:
__state = -1;
if (__this.left == null) goto __yield_value;
__left = __this.left.GetEnumerator();
goto case 1;
case 1:
__state = -2;
if (!__left.MoveNext()) goto __left_dispose;
__current = __left.Current;
__state = 1;
return true;
__left_dispose:
__state = -1;
__left.Dispose();

The compiler-generated temporaries used in the foreach statements are lifted into the __left and __right fields of the enumerator object. The __state field of the enumerator object is carefully updated so that the correct Dispose() method will be called correctly if an exception is thrown. Note that it is not possible to write the translated code with simple foreach statements. end note]
27. Unsafe code

An implementation that does not support unsafe code is required to diagnose any usage of the keyword unsafe.

The remainder of this clause, including all of its subclauses, is conditionally normative.

[Note: The core C# language, as defined in the preceding clauses, differs notably from C and C++ in its omission of pointers as a data type. Instead, C# provides references and the ability to create objects that are managed by a garbage collector. This design, coupled with other features, makes C# a much safer language than C or C++. In the core C# language, it is simply not possible to have an uninitialized variable, a “dangling” pointer, or an expression that indexes an array beyond its bounds. Whole categories of bugs that routinely plague C and C++ programs are thus eliminated.

While practically every pointer type construct in C or C++ has a reference type counterpart in C#, nonetheless, there are situations where access to pointer types becomes a necessity. For example, interfacing with the underlying operating system, accessing a memory-mapped device, or implementing a time-critical algorithm might not be possible or practical without access to pointers. To address this need, C# provides the ability to write unsafe code.

In unsafe code, it is possible to declare and operate on pointers, to perform conversions between pointers and integral types, to take the address of variables, and so forth. In a sense, writing unsafe code is much like writing C code within a C# program.

Unsafe code is in fact a “safe” feature from the perspective of both developers and users. Unsafe code shall be clearly marked with the modifier unsafe, so developers can’t possibly use unsafe features accidentally, and the execution engine works to ensure that unsafe code cannot be executed in an untrusted environment.

end note]

27.1 Unsafe contexts

The unsafe features of C# are available only in unsafe contexts. An unsafe context is introduced by including an unsafe modifier in the declaration of a type or member, or by employing an unsafe-statement:

- A declaration of a class, struct, interface, or delegate can include an unsafe modifier, in which case, the extent of that type-declaration is considered an unsafe context. [Note: If the type-declaration is partial, only that part is an unsafe context. end note]

- A declaration of a field, method, property, event, indexer, operator, instance constructor, finalizer, or static constructor can include an unsafe modifier, in which case, the entire textual extent of that member declaration is considered an unsafe context.

- An unsafe-statement enables the use of an unsafe context within a block. The entire textual extent of the associated block is considered an unsafe context.

The associated grammar extensions are shown below. For brevity, ellipses (...) are used to represent productions that appear in preceding clauses.

[Example: In the following code]
public unsafe struct Node
{
    public int Value;
    public Node* Left;
    public Node* Right;
}
the `unsafe` modifier specified in the struct declaration causes the entire textual extent of the struct declaration to become an unsafe context. Thus, it is possible to declare the `Left` and `Right` fields to be of a pointer type. The example above could also be written

```csharp
public struct Node
{
    public int Value;
    public unsafe Node* Left;
    public unsafe Node* Right;
}
```

Here, the `unsafe` modifiers in the field declarations cause those declarations to be considered unsafe contexts. \[end example\]

Other than establishing an unsafe context, thus permitting the use of pointer types, the `unsafe` modifier has no effect on a type or a member. [Example: In the following code

```csharp
public class A
{
    public unsafe virtual void F() {
        char* p;
    }
}
public class B: A
{
    public override void F() {
        base.F();
    }
}
```

the `unsafe` modifier on the `F` method in `A` simply causes the textual extent of `F` to become an unsafe context in which the unsafe features of the language can be used. In the override of `F` in `B`, there is no need to re-specify the `unsafe` modifier—unless, of course, the `F` method in `B` itself needs access to unsafe features.

The situation is slightly different when a pointer type is part of the method’s signature

```csharp
public unsafe class A
{
    public virtual void F(char* p) { .. }
}
public class B: A
{
    public unsafe override void F(char* p) { .. }
}
```

Here, because `F`’s signature includes a pointer type, it can only be written in an unsafe context. However, the unsafe context can be introduced by either making the entire class unsafe, as is the case in `A`, or by including an `unsafe` modifier in the method declaration, as is the case in `B`. \[end example\]

When the `unsafe` modifier is used on a partial type declaration (§17.1.4), only that particular part is considered an unsafe context.

## 27.2 Pointer types

In an unsafe context, a `type` (§11) can be a `pointer-type` as well as a `value-type`, a `reference-type`, or a `type-parameter`.

```
type:
    value-type
    reference-type
    type-parameter
    pointer-type
```
A **pointer-type** is written as an *unmanaged-type* or the keyword `void`, followed by a `*` token:

```
pointer-type:
  unmanaged-type  *
  void  *

unmanaged-type:
  type
```

The type specified before the `*` in a pointer type is called the **referent type** of the pointer type. It represents the type of the variable to which a value of the pointer type points.

Unlike references (values of reference types), pointers are not tracked by the garbage collector—the garbage collector has no knowledge of pointers and the data to which they point. For this reason a pointer is not permitted to point to a reference or to a struct that contains references, and the referent type of a pointer shall be an *unmanaged-type*.

An *unmanaged-type* is any type that isn’t a reference-type, a type-parameter, or a generic struct-type and contains no fields whose type is not an *unmanaged-type*. In other words, an *unmanaged-type* is one of the following:

- `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, or `bool`.
- Any enum-type.
- Any pointer-type.
- Any non-generic user-defined struct-type that contains fields of *unmanaged-types* only.

[Note: Constructed types and type-parameters are never *unmanaged-types. end note]

The intuitive rule for mixing of pointers and references is that referents of references (objects) are permitted to contain pointers, but referents of pointers are not permitted to contain references.

[Example: Some examples of pointer types are given in the table below:

<table>
<thead>
<tr>
<th>Example</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>byte*</code></td>
<td>Pointer to byte</td>
</tr>
<tr>
<td><code>char*</code></td>
<td>Pointer to char</td>
</tr>
<tr>
<td><code>int**</code></td>
<td>Pointer to pointer to int</td>
</tr>
<tr>
<td><code>int*[]</code></td>
<td>Single-dimensional array of pointers to int</td>
</tr>
<tr>
<td><code>void*</code></td>
<td>Pointer to unknown type</td>
</tr>
</tbody>
</table>

*end example*]

For a given implementation, all pointer types shall have the same size and representation.

[Note: Unlike C and C++, when multiple pointers are declared in the same declaration, in C# the `*` is written along with the underlying type only, not as a prefix punctuator on each pointer name. For example:

```
int* pi, pj;  // NOT as int *pi, *pj;
```

*end note*]

The value of a pointer having type `T*` represents the address of a variable of type `T`. The pointer indirection operator `*` ([§27.5.1](#)) can be used to access this variable. [Example: Given a variable `P` of type `int*`, the expression `*P` denotes the `int` variable found at the address contained in `P`. *end example*]

Like an object reference, a pointer can be `null`. Applying the indirection operator to a `null` pointer results in implementation-defined behavior. A pointer with value `null` is represented by all-bits-zero.
The `void*` type represents a pointer to an unknown type. Because the referent type is unknown, the
indirection operator cannot be applied to a pointer of type `void*`, nor can any arithmetic be performed on
such a pointer. However, a pointer of type `void*` can be cast to any other pointer type (and vice versa) and
compared to values of other pointer types.

Pointer types are a separate category of types. Unlike reference types and value types, pointer types do not
inherit from `object` and no conversions exist between pointer types and `object`. In particular, boxing and
unboxing (§11.3) are not supported for pointers. However, conversions are permitted between different
pointer types and between pointer types and the integral types. This is described in §27.4.

A pointer-type can be used as the type of a volatile field (§17.4.3).

[Note: Although pointers can be passed as ref or out parameters, doing so can cause undefined behavior,
since the pointer might well be set to point to a local variable that no longer exists when the called method
returns, or the fixed object to which it used to point, is no longer fixed. For example:

```csharp
using System;
class Test
{
    static int value = 20;
    unsafe static void F(out int* pi1, ref int* pi2) {
        int i = 10;
        pi1 = &i;
        fixed (int* pj = &value) {
            // ...
            pi2 = pj;
        }
    }
    static void Main() {
        int i = 10;
        unsafe {
            int* px1;
            int* px2 = &i;
            F(out px1, ref px2);
            Console.WriteLine("*px1 = {0}, *px2 = {1}",
                *px1, *px2);  // undefined behavior
        }
    }
}
end note]

A method can return a value of some type, and that type can be a pointer. [Example: When given a pointer to
a contiguous sequence of ints, that sequence's element count, and some other int value, the following
method returns the address of that value in that sequence, if a match occurs; otherwise it returns null:

```csharp
unsafe static int* Find(int* pi, int size, int value) {
    for (int i = 0; i < size; ++i) {
        if (*pi == value) {
            return pi;
        }
        ++pi;
    }
    return null;
}
end example]

In an unsafe context, several constructs are available for operating on pointers:

- The unary `*` operator can be used to perform pointer indirection (§27.5.1).
- The `->` operator can be used to access a member of a struct through a pointer (§27.5.2).
- The `[ ]` operator can be used to index a pointer (§27.5.3).
- The unary `&` operator can be used to obtain the address of a variable (§27.5.4).
• The ++ and -- operators can be used to increment and decrement pointers (§27.5.5).
• The binary + and - operators can be used to perform pointer arithmetic (§27.5.6).
• The ==, !=, <, >, <=, and => operators can be used to compare pointers (§27.5.7).
• The stackalloc operator can be used to allocate memory from the call stack (§27.7).
• The fixed statement can be used to temporarily fix a variable so its address can be obtained (§27.6).

27.3 Fixed and moveable variables

The address-of operator (§27.5.4) and the fixed statement (§27.6) divide variables into two categories: **Fixed variables** and **moveable variables**.

Fixed variables reside in storage locations that are unaffected by operation of the garbage collector. (Examples of fixed variables include local variables, value parameters, and variables created by dereferencing pointers.) On the other hand, moveable variables reside in storage locations that are subject to relocation or disposal by the garbage collector. (Examples of moveable variables include fields in objects and elements of arrays.)

The & operator (§27.5.4) permits the address of a fixed variable to be obtained without restrictions. However, because a moveable variable is subject to relocation or disposal by the garbage collector, the address of a moveable variable can only be obtained using a fixed statement (§27.6), and that address remains valid only for the duration of that fixed statement.

In precise terms, a fixed variable is one of the following:

• A variable resulting from a simple-name (§14.5.2) that refers to a local variable or a value parameter, as long as the variable is not captured by an anonymous method (§14.5.15.3.1).
• A variable resulting from a member-access (§14.5.4) of the form V.I, where V is a fixed variable of a struct-type.
• A variable resulting from a pointer-indirection-expression (§27.5.1) of the form *P, a pointer-member-access (§27.5.2) of the form P->I, or a pointer-element-access (§27.5.3) of the form P[E].

All other variables are classified as moveable variables.

A static field is classified as a moveable variable. Also, a ref or out parameter is classified as a moveable variable, even if the argument given for the parameter is a fixed variable. Finally, a variable produced by dereferencing a pointer is always classified as a fixed variable.

27.4 Pointer conversions

In an unsafe context, the set of available implicit conversions (§13.1) is extended to include the following implicit pointer conversions:

• From any pointer-type to the type void*.
• From the null type (§11.2.7) to any pointer-type.

Additionally, in an unsafe context, the set of available explicit conversions (§13.2) is extended to include the following explicit pointer conversions:

• From any pointer-type to any other pointer-type.
• From sbyte, byte, short, ushort, int, uint, long, or ulong to any pointer-type.
• From any pointer-type to sbyte, byte, short, ushort, int, uint, long, or ulong.

Finally, in an unsafe context, the set of standard implicit conversions (§13.3.1) includes the following pointer conversion:

• From any pointer-type to the type void*. 
Conversions between two pointer types never change the actual pointer value. In other words, a conversion from one pointer type to another has no effect on the underlying address given by the pointer.

When one pointer type is converted to another, if the resulting pointer is not correctly aligned for the pointed-to type, the behavior is undefined if the result is dereferenced. In general, the concept “correctly aligned” is transitive: if a pointer to type A is correctly aligned for a pointer to type B, which, in turn, is correctly aligned for a pointer to type C, then a pointer to type A is correctly aligned for a pointer to type C. [Example: Consider the following case in which a variable having one type is accessed via a pointer to a different type:

```c
char c = 'A';
char* pc = &c;
void* pv = pc;
int* pi = (int*)pv;
int i = *pi;    // undefined
*pi = 123456;  // undefined
```
end example]

When a pointer type is converted to a pointer to `byte`, the result points to the lowest addressed byte of the variable. Successive increments of the result, up to the size of the variable, yield pointers to the remaining bytes of that variable. [Example: The following method displays each of the eight bytes in a `double` as a hexadecimal value:

```c
using System;
class Test
{
    static void Main() {
        double d = 123.456e23;
        unsafe {
            byte* pb = (byte*)&d;
            for (int i = 0; i < sizeof(double); ++i)
                Console.Write(" {0,2:X}", (uint)(*pb++));
            Console.WriteLine();
        }
    }
}
```
end example]

Mappings between pointers and integers are implementation-defined. [Note: However, on 32- and 64-bit CPU architectures with a linear address space, conversions of pointers to or from integral types typically behave exactly like conversions of `uint` or `ulong` values, respectively, to or from those integral types. end note]

### 27.5 Pointers in expressions

In an unsafe context, an expression can yield a result of a pointer type, but outside an unsafe context, it is a compile-time error for an expression to be of a pointer type. In precise terms, outside an unsafe context a compile-time error occurs if any `simple-name` (§14.5.2), `member-access` (§14.5.4), `invocation-expression` (§14.5.5), or `element-access` (§14.5.6) is of a pointer type.

The `primary-no-array-creation-expression` (§14.5) productions permit the following additional construct:

```
primary-no-array-creation-expression:
...
sizeof-expression
```

In an unsafe context, the `primary-no-array-creation-expression` (§14.5) and `unary-expression` (§14.5.14) productions permit the following additional constructs:

```
primary-no-array-creation-expression:
...
pointer-member-access
pointer-element-access
```
unary-expression:
  ...
  pointer-indirection-expression
  addressof-expression

These constructs are described in the following subclauses.

There are also several predefined unary and binary operators for pointers. When applying unary or binary operator overload resolution, if none of the actual operands is a pointer type, then any predefined unary or binary operator with a pointer parameter type is removed from consideration.

[Note: The precedence and associativity of the unsafe operators is implied by the grammar. end note]

27.5.1 Pointer indirection

A pointer-indirection-expression consists of an asterisk (*) followed by a unary-expression.

pointer-indirection-expression:
  * unary-expression

The unary * operator denotes pointer indirection and is used to obtain the variable to which a pointer points. The result of evaluating *P, where P is an expression of a pointer type T*, is a variable of type T. It is a compile-time error to apply the unary * operator to an expression of type void* or to an expression that isn’t of a pointer type.

The effect of applying the unary * operator to a null pointer is implementation-defined. In particular, there is no guarantee that this operation throws a System.NullReferenceException.

If an invalid value has been assigned to the pointer, the behavior of the unary * operator is undefined. [Note: Among the invalid values for dereferencing a pointer by the unary * operator are an address inappropriately aligned for the type pointed to (see example in §27.4), and the address of a variable after the end of its lifetime. end note]

For purposes of definite assignment analysis, a variable produced by evaluating an expression of the form *P is considered initially assigned (§12.3.1).

27.5.2 Pointer member access

A pointer-member-access consists of a primary-expression, followed by a “->” token, followed by an identifier.

pointer-member-access:
  primary-expression -> identifier type-argument-listopt

In a pointer member access of the form P->I, P shall be an expression of a pointer type other than void*, and I shall denote an accessible member of the type to which P points.

A pointer member access of the form P->I is evaluated exactly as (*P).I. For a description of the pointer indirection operator (*), see §27.5.1. For a description of the member access operator (.), see §14.5.4.

[Example: In the following code
  struct Point
  {
    public int x;
    public int y;
    public override string ToString() {
      return "(" + x + "," + y + ")";
    }
  }
  using System;
```csharp
class Test {
    static void Main() {
        Point point;
        unsafe {
            Point* p = &point;
            p->x = 10;
            p->y = 20;
            Console.WriteLine(p->ToString());
        }
    }
}
```

the -> operator is used to access fields and invoke a method of a struct through a pointer. Because the operation P->I is precisely equivalent to (*P).I, the Main method could equally well have been written:
```
using System;
class Test {
    static void Main() {
        Point point;
        unsafe {
            Point* p = &point;
            (*p).x = 10;
            (*p).y = 20;
            Console.WriteLine((*p).ToString());
        }
    }
}
```

end example]

27.5.3 Pointer element access

A pointer-element-access consists of a primary-no-array-creation-expression followed by an expression enclosed in "[" and "]".

```
pointer-element-access:
    primary-no-array-creation-expression [ expression ]
```

In a pointer element access of the form P[E], P shall be an expression of a pointer type other than void*, and E shall be an expression of a type that can be implicitly converted to int, uint, long, or ulong.

A pointer element access of the form P[E] is evaluated exactly as *(P + E). For a description of the pointer indirection operator (*), see §27.5.1. For a description of the pointer addition operator (+), see §27.5.6.

[Example: In the following code

```csharp
class Test {
    static void Main() {
        unsafe {
            char* p = stackalloc char[256];
            for (int i = 0; i < 256; i++) p[i] = (char)i;
        }
    }
}
```

a pointer element access is used to initialize the character buffer in a for loop. Because the operation P[E] is precisely equivalent to *(P + E), the example could equally well have been written:
class Test
{
    static void Main()
    {
        unsafe {
            char* p = stackalloc char[256];
            for (int i = 0; i < 256; i++) *(p + i) = (char)i;
        }
    }
}

The pointer element access operator does not check for out-of-bounds errors and the behavior when accessing an out-of-bounds element is undefined. [Note: This is the same as C and C++. end note]

27.5.4 The address-of operator

An addressof-expression consists of an ampersand (&) followed by a unary-expression.

addressof-expression:
   & unary-expression

Given an expression E which is of a type T and is classified as a fixed variable (§27.3), the construct &E computes the address of the variable given by E. The type of the result is T* and is classified as a value. A compile-time error occurs if E is not classified as a variable, if E is classified as a volatile field (§17.4.3), or if E denotes a moveable variable. In the last case, a fixed statement (§27.6) can be used to temporarily “fix” the variable before obtaining its address.

The & operator does not require its argument to be definitely assigned, but following an & operation, the variable to which the operator is applied is considered definitely assigned in the execution path in which the operation occurs. It is the responsibility of the programmer to ensure that correct initialization of the variable actually does take place in this situation.

[Example: In the following code

```c#
using System;
class Test
{
    static void Main()
    {
        int i;
        unsafe {
            int* p = &i;
            *p = 123;
        }
        Console.WriteLine(i);
    }
}
```

i is considered definitely assigned following the &i operation used to initialize p. The assignment to *p in effect initializes i, but the inclusion of this initialization is the responsibility of the programmer, and no compile-time error would occur if the assignment were removed. end example]

[Note: The rules of definite assignment for the & operator exist such that redundant initialization of local variables can be avoided. For example, many external APIs take a pointer to a structure which is filled in by the API. Calls to such APIs typically pass the address of a local struct variable, and without the rule, redundant initialization of the struct variable would be required. end note]

[Note: As stated in §14.5.4, outside an instance constructor or static constructor for a struct or class that defines a readonly field, that field is considered a value, not a variable. As such, its address cannot be taken. Similarly, the address of a constant cannot be taken. end note]

When a local variable, value parameter, or parameter array is captured by an anonymous method (§14.5.15.3.1), that local variable, parameter, or parameter array is no longer considered to be a fixed variable (§27.3), but is instead considered to be a moveable variable. Thus it is an error for any unsafe
code to take the address of a local variable, value parameter, or parameter array that has been captured by an anonymous method.

27.5.5 Pointer increment and decrement

In an unsafe context, the ++ and -- operators (§14.5.9 and §14.6.5) can be applied to pointer variables of all types except void*. Thus, for every pointer type T*, the following operators are implicitly defined:

\[
\begin{align*}
T* \text{ operator } & \quad ++(T* \ x); \\
T* \text{ operator } & \quad --(T* \ x);
\end{align*}
\]

The operators produce the same results as \(x+1\) and \(x-1\), respectively (§27.5.6). In other words, for a pointer variable of type T*, the ++ operator adds sizeof(T) to the address contained in the variable, and the -- operator subtracts sizeof(T) from the address contained in the variable.

If a pointer increment or decrement operation overflows the domain of the pointer type, the result is implementation-defined, but no exceptions are produced.

27.5.6 Pointer arithmetic

In an unsafe context, the + operator (§14.7.4) and - operator (§14.7.5) can be applied to values of all pointer types except void*. Thus, for every pointer type T*, the following operators are implicitly defined:

\[
\begin{align*}
T* \text{ operator } +&(T* \ x, \text{ int } y); \\
T* \text{ operator } +&(T* \ x, \text{ uint } y); \\
T* \text{ operator } +&(T* \ x, \text{ long } y); \\
T* \text{ operator } +&(T* \ x, \text{ ulong } y); \\
T* \text{ operator } +&(\text{ int } x, \text{ T* } y); \\
T* \text{ operator } +&(\text{ uint } x, \text{ T* } y); \\
T* \text{ operator } +&(\text{ long } x, \text{ T* } y); \\
T* \text{ operator } +&(\text{ ulong } x, \text{ T* } y); \\
T* \text{ operator } -&(T* \ x, \text{ int } y); \\
T* \text{ operator } -&(T* \ x, \text{ uint } y); \\
T* \text{ operator } -&(T* \ x, \text{ long } y); \\
T* \text{ operator } -&(T* \ x, \text{ ulong } y); \\
\text{ long operator } -&(T* \ x, \text{ T* } y);
\end{align*}
\]

Given an expression P of a pointer type T* and an expression N of type int, uint, long, or ulong, the expressions \(P + N\) and \(N + P\) compute the pointer value of type T* that results from adding \(N \times \text{sizeof}(T)\) to the address given by P. Likewise, the expression \(P - N\) computes the pointer value of type T* that results from subtracting \(N \times \text{sizeof}(T)\) from the address given by P.

Given two expressions, P and Q, of a pointer type T*, the expression \(P - Q\) computes the difference between the addresses given by P and Q and then divides that difference by sizeof(T). The type of the result is always long. In effect, \(P - Q\) is computed as \(((\text{long})(P) - (\text{long})(Q)) / \text{sizeof}(T)\).

[Example:

using System;

class Test
{
    static void Main()
    {
        unsafe
        {
            int* values = stackalloc int[20];
            int* p = &values[1];
            int* q = &values[15];
            Console.WriteLine("p - q = \{0\}\n", p - q);
            Console.WriteLine("q - p = \{0\}\n", q - p);
        }
    }
}

which produces the output:
\[ p - q = -14 \\
q - p = 14 \]

end example]

If a pointer arithmetic operation overflows the domain of the pointer type, the result is truncated in an implementation-defined fashion, but no exceptions are produced.

27.5.7 Pointer comparison

In an unsafe context, the ==, !=, <, >, <=, and => operators (§14.9) can be applied to values of all pointer types. The pointer comparison operators are:

\[ \text{bool operator } == (\text{void* x, void* y}); \]
\[ \text{bool operator } != (\text{void* x, void* y}); \]
\[ \text{bool operator } < (\text{void* x, void* y}); \]
\[ \text{bool operator } > (\text{void* x, void* y}); \]
\[ \text{bool operator } <= (\text{void* x, void* y}); \]
\[ \text{bool operator } >= (\text{void* x, void* y}); \]

Because an implicit conversion exists from any pointer type to the \textit{void*} type, operands of any pointer type can be compared using these operators. The comparison operators compare the addresses given by the two operands as if they were unsigned integers.

27.5.8 The \texttt{sizeof} operator

The \texttt{sizeof} operator returns the number of 8-bit bytes occupied by a variable of a given type. The type specified as an operand to \texttt{sizeof} shall be an \textit{unmanaged-type} (§27.2).

\texttt{sizeof-expression:}
\begin{verbatim}
 sizeof ( unmanaged-type )
\end{verbatim}

For the predefined types specified in §14.5.12 the \texttt{sizeof} operator yields a constant \texttt{int} value, and the \texttt{sizeof-expression} is allowed both inside and outside an unsafe context.

For all other types, the result of the \texttt{sizeof} operator is implementation-defined and is classified as an \texttt{int} value rather than an \texttt{int} constant, and the \texttt{sizeof-expression} shall be inside an unsafe context.

The order in which members are packed into a struct is unspecified.

For alignment purposes, there can be unnamed padding at the beginning of a struct, within a struct, and at the end of the struct. The contents of the bits used as padding are indeterminate.

When applied to an operand that has struct type, the result is the total number of bytes in a variable of that type, including any padding.

27.6 The \texttt{fixed} statement

In an unsafe context, the \texttt{embedded-statement} (§15) production permits an additional construct, the \texttt{fixed} statement, which is used to “fix” a moveable variable such that its address remains constant for the duration of the statement.

\texttt{embedded-statement:}
\begin{verbatim}
... 
 fixed-statement 
\end{verbatim}

\texttt{fixed-statement:}
\begin{verbatim}
 fixed ( pointer-type fixed-pointer-declarators ) embedded-statement 
\end{verbatim}

\texttt{fixed-pointer-declarators:}
\begin{verbatim}
 fixed-pointer-declarator 
 fixed-pointer-declarators , fixed-pointer-declarator 
\end{verbatim}

\texttt{fixed-pointer-declarator:}
\begin{verbatim}
 identifier = fixed-pointer-initializer 
\end{verbatim}
Each fixed-pointer-declarator declares a local variable of the given pointer-type and initializes that local variable with the address computed by the corresponding fixed-pointer-initializer. A local variable declared in a fixed statement is accessible in any fixed-pointer-initializers occurring to the right of that variable’s declaration, and in the embedded-statement of the fixed statement. A local variable declared by a fixed statement is considered read-only. A compile-time error occurs if the embedded statement attempts to modify this local variable (via assignment or the ++ and -- operators) or pass it as a ref or out parameter.

It is an error to use a captured local variable (§14.5.15.3.1), value parameter, or parameter array in a fixed statement.

A fixed-pointer-initializer can be one of the following:

- The token “&” followed by a variable-reference (§12.3.3.27) to a moveable variable (§27.3) of an unmanaged type T, provided the type T* is implicitly convertible to the pointer type given in the fixed statement. In this case, the initializer computes the address of the given variable, and the variable is guaranteed to remain at a fixed address for the duration of the fixed statement.

- An expression of an array-type with elements of an unmanaged type T, provided the type T* is implicitly convertible to the pointer type given in the fixed statement. In this case, the initializer computes the address of the first element in the array, and the entire array is guaranteed to remain at a fixed address for the duration of the fixed statement. The behavior of the fixed statement is implementation-defined if the array expression is null or if the array has zero elements.

- An expression of type string, provided the type char* is implicitly convertible to the pointer type given in the fixed statement. In this case, the initializer computes the address of the first character in the string, and the entire string is guaranteed to remain at a fixed address for the duration of the fixed statement. The behavior of the fixed statement is implementation-defined if the string expression is null.

For each address computed by a fixed-pointer-initializer the fixed statement ensures that the variable referenced by the address is not subject to relocation or disposal by the garbage collector for the duration of the fixed statement. [Example: If the address computed by a fixed-pointer-initializer references a field of an object or an element of an array instance, the fixed statement guarantees that the containing object instance is not relocated or disposed of during the lifetime of the statement. end example]

It is the programmer’s responsibility to ensure that pointers created by fixed statements do not survive beyond execution of those statements. [Example: When pointers created by fixed statements are passed to external APIs, it is the programmer’s responsibility to ensure that the APIs retain no memory of these pointers. end example]

Fixed objects can cause fragmentation of the heap (because they can’t be moved). For that reason, objects should be fixed only when necessary and then only for the shortest amount of time possible. [Example: The example

```csharp
class Test
{
    static int x;
    int y;
    unsafe static void F(int* p) {
        *p = 1;
    }
}
```
static void Main() {
    Test t = new Test();
    int[] a = new int[10];
    unsafe {
        fixed (int* p = &x) F(p);
        fixed (int* p = &t.y) F(p);
        fixed (int* p = &a[0]) F(p);
        fixed (int* p = a) F(p);
    }
}

demonstrates several uses of the fixed statement. The first statement fixes and obtains the address of a
static field, the second statement fixes and obtains the address of an instance field, and the third statement
fixes and obtains the address of an array element. In each case, it would have been an error to use the regular
& operator since the variables are all classified as moveable variables.

The third and fourth fixed statements in the example above produce identical results. In general, for an
array instance a, specifying &a[0] in a fixed statement is the same as simply specifying a.

Here’s another example of the fixed statement, this time using string:

class Test
{
    static string name = "xx";
    unsafe static void F(char* p) {
        for (int i = 0; p[i] != '\0'; ++i)
            Console.WriteLine(p[i]);
    }
    static void Main() {
        unsafe {
            fixed (char* p = name) F(p);
            fixed (char* p = "xx") F(p);
        }
    }
}

end example

In an unsafe context, array elements of single-dimensional arrays are stored in increasing index order,
starting with index 0 and ending with index Length – 1. For multi-dimensional arrays, array elements are
stored such that the indices of the rightmost dimension are increased first, then the next left dimension, and
so on to the left.

Within a fixed statement that obtains a pointer p to an array instance a, the pointer values ranging from p
to p + a.Length - 1 represent addresses of the elements in the array. Likewise, the variables ranging from
p[0] to p[a.Length - 1] represent the actual array elements. Given the way in which arrays are stored,
we can treat an array of any dimension as though it were linear. [Example:

using System;
class Test
{
    static void Main() {
        int[,] a = new int[2,3,4];
        unsafe {
            fixed (int* p = a) {
                for (int i = 0; i < a.Length; ++i) // treat as linear
                    p[i] = i;
            }
        }
    }
}
unsafe code

```csharp
for (int i = 0; i < 2; ++i)
    for (int j = 0; j < 3; ++j)
        for (int k = 0; k < 4; ++k)
            Console.Write("[{0},{1},{2}] = {3} ", i, j, k, a[i, j, k]);

Console.WriteLine();
```

which produces the output:

```
[0,0,0] = 0 [0,0,1] = 1 [0,0,2] = 2 [0,0,3] = 3
[0,1,0] = 4 [0,1,1] = 5 [0,1,2] = 6 [0,1,3] = 7
[0,2,0] = 8 [0,2,1] = 9 [0,2,2] = 10 [0,2,3] = 11
[1,0,0] = 12 [1,0,1] = 13 [1,0,2] = 14 [1,0,3] = 15
[1,1,0] = 16 [1,1,1] = 17 [1,1,2] = 18 [1,1,3] = 19
[1,2,0] = 20 [1,2,1] = 21 [1,2,2] = 22 [1,2,3] = 23
```

end example

[Example: In the following code]

```csharp
class Test
{
    unsafe static void Fill(int* p, int count, int value) {
        for (; count != 0; count--) *p++ = value;
    }

    static void Main() {
        int[] a = new int[100];
        unsafe {
            fixed (int* p = a) Fill(p, 100, -1);
        }
    }
}
```

a **fixed** statement is used to fix an array so its address can be passed to a method that takes a pointer. *end example*

A **char** value produced by fixing a non-null string instance always points to a null-terminated string. Within a fixed statement that obtains a pointer *p* to a string instance *s*, the pointer values ranging from *p* to *p* + *s*.Length - 1 represent addresses of the characters in the string, and the pointer value *p* + *s*.Length always points to a null character (the character with value '\0').

Modifying objects of managed type through fixed pointers can result in undefined behavior. *[Note: For example, because strings are immutable, it is the programmer’s responsibility to ensure that the characters referenced by a pointer to a fixed string are not modified. end note]*

*[Note: The automatic null-termination of strings is particularly convenient when calling external APIs that expect “C-style” strings. Note, however, that a string instance is permitted to contain null characters. If such null characters are present, the string will appear truncated when treated as a null-terminated char*. *end note]*

### 27.7 Stack allocation

In an unsafe context, a local variable declaration (§15.5.1) can include a stack allocation initializer, which allocates memory from the call stack.

```
local-variable-initializer:
    expression
    array-initializer
    stackalloc-initializer

stackalloc-initializer:
    stackalloc unmanaged-type [ expression ]
```
The *unmanaged-type* indicates the type of the items that will be stored in the newly allocated location, and the *expression* indicates the number of these items. Taken together, these specify the required allocation size. Since the size of a stack allocation cannot be negative, it is a compile-time error to specify the number of items as a *constant-expression* that evaluates to a negative value.

A stack allocation initializer of the form `stackalloc T[E]` requires `T` to be an unmanaged type (§27.2) and `E` to be an expression convertible to type `int`. The construct allocates `E * sizeof(T)` bytes from the call stack and returns a pointer, of type `T*`, to the newly allocated block. If `E` is a negative value, then the behavior is undefined. If `E` is zero, then no allocation is made, and the pointer returned is implementation-defined. If there is not enough memory available to allocate a block of the given size, a `System.StackOverflowException` is thrown.

The content of the newly allocated memory is undefined.

Stack allocation initializers are not permitted in catch or finally blocks (§15.10).

[Note: There is no way to explicitly free memory allocated using `stackalloc`. *end note*] All stack-allocated memory blocks created during the execution of a function member are automatically discarded when that function member returns. [Note: This corresponds to the `alloca` function, an extension commonly found in C and C++ implementations. *end note*]

[Example: In the following code]
```csharp
using System;
class Test
{
    static string IntToString(int value) {
        int n = value >= 0 ? value : -value;
        unsafe {
            char* buffer = stackalloc char[16];
            char* p = buffer + 16;
            do {
                n /= 10;
                --p = (char)(n % 10 + '0');
            } while (n != 0);
            if (value < 0) *--p = '-';
            return new string(p, 0, (int)(buffer + 16 - p));
        }
    }
    static void Main() {
        Console.WriteLine(IntToString(12345));
        Console.WriteLine(IntToString(-999));
    }
}
```

a `stackalloc` initializer is used in the `IntToString` method to allocate a buffer of 16 characters on the stack. The buffer is automatically discarded when the method returns. *end example*

### 27.8 Dynamic memory allocation

Except for the `stackalloc` operator, C# provides no predefined constructs for managing non-garbage collected memory. Such services are typically provided by supporting class libraries or imported directly from the underlying operating system. [Example: The `Memory` static class below illustrates how the heap functions of an underlying operating system might be accessed from C#:

```csharp
using System;
using System.Runtime.InteropServices;
public unsafe static class Memory
{
    // Handle for the process heap. This handle is used in all calls to
    // the HeapXXX APIs in the methods below.
    static int ph = GetProcessHeap();
```
// Allocates a memory block of the given size. The allocated memory is
// automatically initialized to zero.
public static void* Alloc(int size) {
    void* result = HeapAlloc(ph, HEAP_ZERO_MEMORY, size);
    if (result == null) throw new OutOfMemoryException();
    return result;
}

// Copies count bytes from src to dst. The source and destination
// blocks are permitted to overlap.
public static void Copy(void* src, void* dst, int count) {
    byte* ps = (byte*)src;
    byte* pd = (byte*)dst;
    if (ps > pd) {
        for (; count != 0; count--) *pd++ = *ps++;
    } else if (ps < pd) {
        for (ps += count, pd += count; count != 0; count--)
            *--pd = *--ps;
    }
}

// Frees a memory block.
public static void Free(void* block) {
    if (!HeapFree(ph, 0, block)) throw new InvalidOperationException();
}

// Re-allocates a memory block. If the reallocation request is for a
// larger size, the additional region of memory is automatically
// initialized to zero.
public static void* ReAlloc(void* block, int size) {
    void* result = HeapReAlloc(ph, HEAP_ZERO_MEMORY, block, size);
    if (result == null) throw new OutOfMemoryException();
    return result;
}

// Returns the size of a memory block.
public static int SizeOf(void* block) {
    int result = HeapSize(ph, 0, block);
    if (result == -1) throw new InvalidOperationException();
    return result;
}

// Heap API flags
const int HEAP_ZERO_MEMORY = 0x00000008;

// Heap API functions
[DllImport("kernel32")]
static extern int GetProcessHeap();

[DllImport("kernel32")]
static extern void* HeapAlloc(int hHeap, int flags, int size);

[DllImport("kernel32")]
static extern bool HeapFree(int hHeap, int flags, void* block);

[DllImport("kernel32")]
static extern void* HeapReAlloc(int hHeap, int flags,
void* block, int size);

[DllImport("kernel32")]
static extern int HeapSize(int hHeap, int flags, void* block);

An example that uses the Memory class is given below:
class Test
{
    static void Main()
    {
        unsafe
        {
            byte* buffer = (byte*)Memory.Alloc(256);
            for (int i = 0; i < 256; i++) buffer[i] = (byte)i;
            byte[] array = new byte[256];
            fixed (byte* p = array) Memory.Copy(buffer, p, 256);
            Memory.Free(buffer);
            for (int i = 0; i < 256; i++) Console.WriteLine(array[i]);
        }
    }
}

The example allocates 256 bytes of memory through `Memory.Alloc` and initializes the memory block with values increasing from 0 to 255. It then allocates a 256-element byte array and uses `Memory.Copy` to copy the contents of the memory block into the byte array. Finally, the memory block is freed using `Memory.Free` and the contents of the byte array are output on the console. \textit{end example}

Annex B. Portability issues

This clause is informative.

This annex collects some information about portability that appears in this International Standard.

B.1 Undefined behavior

A program that does not contain any occurrences of the `unsafe` modifier cannot exhibit any undefined behavior.

The behavior is undefined in the following circumstances:

1. When dereferencing the result of converting one pointer type to another and the resulting pointer is not correctly aligned for the pointed-to type. (§27.4)
2. When the unary * operator is applied to a pointer containing an invalid value (§27.5.1).
3. When a pointer is subscripted to access an out-of-bounds element (§27.5.3).
4. Modifying objects of managed type through fixed pointers (§27.6)
5. The initial content of memory allocated by `stackalloc` (§27.7).
6. Attempting to allocate a negative number of items using `stackalloc` (§27.7).

B.2 Implementation-defined behavior

A conforming implementation is required to document its choice of behavior in each of the areas listed in this subclause. The following are implementation-defined:

1. The behavior when an identifier not in Normalization Form C is encountered (§9.4.2).
2. The purpose of a `line-indicator` with an `identifier-or-keyword` whose value does not equal `default` (§9.5.7).
3. The interpretation of the `input-characters` in the `pp-pragmas-text` of a `#pragma` directive (§9.5.8).
4. The values of any application parameters passed to `main` by the host environment prior to application startup (§10.1).
5. Whether a `System.ArithmeticException` (or a subclass thereof) is thrown or the overflow goes unreported with the resulting value being that of the left operand, when in an unchecked context and the left operand of an integer division is the maximum negative int or long value and the right operand is −1 (§14.7.2).
6. When a `System.ArithmeticException` (or a subclass thereof) is thrown when performing a decimal remainder operation (§14.7.3).
7. The mechanism by which linkage to an external function is achieved (§17.5.7).
8. The impact of thread termination when no matching catch clause is found for an exception and the code that initially started that thread is reached. (§23.3)
9. The purpose of attribute target specifiers other than those identified by this standard (§24.2).
10. The mappings between pointers and integers (§27.4).
11. The effect of applying the unary * operator to a `null` pointer (§27.5.1).
12. The behavior when pointer arithmetic overflows the domain of the pointer type (§27.5.5).
13. The result of the `sizeof` operator for nonpre-defined value types (§27.5.8).

14. The behavior of the `fixed` statement if the array expression is null or if the array has zero elements (§27.6).

15. The behavior of the `fixed` statement if the string expression is null (§27.6).

16. The value returned when a stack allocation of size zero is made (§27.7).

**B.3 Unspecified behavior**

1. The time at which the finalizer (if any) for an object is run, once that object has become eligible for finalization (§10.9).

2. The value of the result when converting out-of-range values from `float` or `double` values to an integral type in an unchecked context (§13.2.1).

3. The layout of arrays, except in an unsafe context (§14.5.10.2).

4. Whether there is any way to execute the block of an anonymous method other than through evaluation and invocation of the `anonymous-method-expression` (§14.5.15.2).

5. The invocation list of a delegate produced from an `anonymous-method-expression` contains a single entry. The exact target object and target method of the delegate are unspecified (§14.5.15.4).

6. The exact timing of static field initialization (§17.4.5.1).

7. The behavior of uncaught exceptions that occur during finalizer execution (§23.3).

8. The attributes of a type declared in multiple parts are determined by combining, in an unspecified order, the attributes of each of its parts (§24.2).

9. The order in which members are packed into a struct (§27.5.8).

10. When an enumerator object is in the `running` state, the result of invoking `MoveNext` is unspecified (§26.2.1).

11. When an enumerator object is in the `before`, `running`, or `after` states, the result of accessing `Current` is unspecified (§26.2.2).

12. When an enumerator object is in the `running` state, the result of invoking `Dispose` is unspecified (§26.2.3).

**B.4 Other Issues**

1. The exact results of floating-point expression evaluation can vary from one implementation to another, because an implementation is permitted to evaluate such expressions using a greater range and/or precision than is required. (§11.1.6)

2. The CLI reserves certain signatures for compatibility with other programming languages. (§17.2.7)

Annex D. Standard Library

A conforming C# implementation shall provide a minimum set of types having specific semantics. These types and their members are listed here, in alphabetical order by namespace and type. For a formal definition of these types and their members, refer to ISO/IEC 23271:2005 Common Language Infrastructure (CLI), Partition IV; Base Class Library (BCL), Extended Numerics Library, and Extended Array Library, which are included by reference in this International Standard.

Type names beginning with System. are intended for use by the Standard Library: Such names not currently in use might be defined in a future version of this International Standard.

This text is informative.

The standard library is intended to be the minimum set of types and members required by a conforming C# implementation. As such, it contains only those members which are explicitly required by the C# language specification.

It is expected that a conforming C# implementation will supply a significantly more extensive library that enables useful programs to be written. For example, a conforming implementation might extend this library by

- Adding namespaces.
- Adding types.
- Adding members to non-interface types.
- Having struct and class types implement additional interfaces.
- Adding attributes (other than the ConditionalAttribute) to existing types and members.

C# provides a mechanism for programmers to document their code using a special comment syntax that contains XML text. Comments using such syntax are called documentation comments. The XML generation tool is called the documentation generator. (This generator could be, but need not be, the C# compiler itself.) The output produced by the documentation generator is called the documentation file. A documentation file is used as input to a documentation viewer; a tool intended to produce some sort of visual display of type information and its associated documentation.

A conforming C# compiler is not required to check the syntax of documentation comments; such comments are simply ordinary comments. A conforming compiler is permitted to do such checking, however.

This specification suggests a set of standard tags to be used in documentation comments. For C# implementations targeting the CLI, it also provides information about the documentation generator and the format of the documentation file. No information is provided about the documentation viewer.

E.1 Introduction

Comments having a special form can be used to direct a tool to produce XML from those comments and the source code elements, which they precede. Such comments are single-line comments of the form /// … or delimited comments of the form /** … */. They must immediately precede a user-defined type (such as a class, delegate, or interface) or a member (such as a field, event, property, or method) that they annotate. Attribute sections are considered part of declarations, so documentation comments must precede attributes applied to a type or member.

Syntax:

\[\text{single-line-doc-comment::} \]
\[\text{/// input-characters}_{\text{opt}} \]

\[\text{delimited-doc-comment::} \]
\[/** \text{delimited-comment-characters}_{\text{opt}} */ \]

In a single-line-doc-comment, if there is a whitespace character following the /// characters on each of the single-line-doc-comments adjacent to the current single-line-doc-comment, then that whitespace character is not included in the XML output.

In a delimited-doc-comment, if the first non-whitespace character on the second line is an asterisk and the same pattern of optional whitespace characters and an asterisk character is repeated at the beginning of each of the lines within the delimited-doc-comment, then the characters of the repeated pattern are not included in the XML output. The pattern can include whitespace characters after, as well as before, the asterisk character.

Example:

```csharp
/**
 * <remarks>
 * Class <c>Point</c> models a point in a two-dimensional plane.
 * </remarks>
 */

public class Point
{
    /// <remarks>Method <c>Draw</c> renders the point.</remarks>
    void Draw() { ... }
}
```
The text within documentation comments must be well formed according to the rules of XML (http://www.w3.org/TR/REC-xml). If the XML is ill formed, a warning is generated and the documentation file will contain a comment saying that an error was encountered.

Although developers are free to create their own set of tags, a recommended set is defined in §E.2. Some of the recommended tags have special meanings:

- The `<param>` tag is used to describe parameters. If such a tag is used, the documentation generator must verify that the specified parameter exists and that all parameters are described in documentation comments. If such verification fails, the documentation generator issues a warning.

- The `cref` attribute can be attached to any tag to provide a reference to a code element. The documentation generator must verify that this code element exists. If the verification fails, the documentation generator issues a warning. When looking for a name described in a `cref` attribute, the documentation generator must respect namespace visibility according to `using` statements appearing within the source code. For code elements that contain code that uses generics, the normal generics syntax, for instance `List<T>`, cannot be used because it produces invalid XML. Instead, curly braces can be used, such as `<see cref="List{T}"/>`, or the normal XML escape syntax `&lt;` and `&gt;` for instance as in `List&lt;T&gt;`. Members of generic types are referred to as `List{T}.Add(T)`. The variable `T` in `Add(T)` is bound by the type parameter `T` in `List{T}`. Similarly, the parameter type `T` of the generic method `Sort{T}(T[])` is bound by the type-parameter `T`. In general, a generic method in a generic class is referred to as `C{S}.F{T}(S, List{T}, U)`, here the parameter `S` is bound by the type parameter of the class `C{S}` and the `T` in `List{T}` is bound by the type parameter of the generic method `F{T}`, the parameter type `U` is free.

- The `<summary>` tag is intended to be used by a documentation viewer to display additional information about a type or member.

Note carefully that the documentation file does not provide full information about the type and members (for example, it does not contain any type information). To get such information about a type or member, the documentation file must be used in conjunction with reflection on the runtime type or member.

### E.2 Recommended tags

The documentation generator must accept and process any tag that is valid according to the rules of XML. The following tags provide commonly used functionality in user documentation. (Of course, other tags are possible.)
### E.2.1 `<c>`

This tag provides a mechanism to indicate that a fragment of text within a description should be set in a special font such as that used for a block of code. For lines of actual code, use `<code>` (§E.2.2).

**Syntax:**

```xml
<c>text to be set like code</c>
```

**Example:**

```csharp
/// <remarks>
///   Class <c>Point</c> models a point in a two-dimensional plane.
/// </remarks>
public class Point
{
    ...
}
```

### E.2.2 `<code>`

This tag is used to set one or more lines of source code or program output in some special font. For small code fragments in narrative, use `<c>` (§E.2.1).

**Syntax:**

```
<code>source code or program output</code>
```

**Example:**

```csharp
```

public void Translate(int xor, int yor) {
    X += xor;
    Y += yor;
}

E.2.3 <example>

See <code> (§E.2.2) for an example.

E.2.4 <exception>
This tag provides a way to document the exceptions a method can throw.

    <description> description</description>
  </listheader>
  <item>

**E.3 Processing the documentation file**

The following information is intended for C# implementations targeting the CLI.

The documentation generator generates an ID string for each element in the source code that is tagged with a documentation comment. This ID string uniquely identifies a source element. A documentation viewer can use an ID string to identify the corresponding metadata/reflection item to which the documentation applies.

The documentation file is not a hierarchical representation of the source code; rather, it is a flat list with a generated ID string for each element.

**E.3.1 ID string format**

The documentation generator observes the following rules when it generates the ID strings:

- No white space is placed in the string.
- The first part of the string identifies the kind of member being documented, via a single character followed by a colon. The following kinds of members are defined:
<table>
<thead>
<tr>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>E</td>
<td>Event</td>
</tr>
<tr>
<td>F</td>
<td>Field</td>
</tr>
<tr>
<td>M</td>
<td>Method (including constructors, finalizers, and operators)</td>
</tr>
<tr>
<td>N</td>
<td>Namespace</td>
</tr>
<tr>
<td>P</td>
<td>Property (including indexers)</td>
</tr>
<tr>
<td>T</td>
<td>Type (such as class, delegate, enum, interface, and struct)</td>
</tr>
<tr>
<td></td>
<td>! Error string; the rest of the string provides information about the error. For example, the documentation generator generates error information for links that cannot be resolved.</td>
</tr>
</tbody>
</table>

- The second part of the string is the fully qualified name of the element, starting at the root of the namespace. The name of the element, its enclosing type(s), and namespace are separated by periods. If the name of the item itself has periods, they are replaced by the NUMBER SIGN # (U+0023). (It is assumed that no element has this character in its name.)

- For methods and properties with arguments, the argument list follows, enclosed in parentheses. For those without arguments, the parentheses are omitted. The arguments are separated by commas. The encoding of each argument is the same as a CLI signature, as follows: Arguments are represented by their complete documentation name, which is based on their fully qualified name. For example, int becomes System.Int32, string becomes System.String, object becomes System.Object, and so on. Arguments that define generic type parameters have an appended grave accent character “`”, followed by the number of type parameters; for example, C`1. For nested types, the number is based upon the number of new type parameters on the nested type; for example, C`1.NestedC`2. Arguments having the out or ref modifier have an @ following their type name. Arguments passed by value or via params have no special notation. Arguments that are arrays are represented as [lowerbound : size , … , lowerbound : size] where the number of commas is the rank less one, and the lower bounds and size of each dimension, if known, are represented in decimal. If a lower bound or size is not specified, it is omitted. If the lower bound and size for a particular dimension are omitted, the “:” is omitted as well. Jagged arrays are represented by one “[]” per level. Arguments that have pointer types other than void are represented using a * following the type name. A void pointer is represented using a type name of System.Void. Arguments that refer to generic type parameters on types are encoded using a single grave accent character “`” followed by the zero-based index of the type parameter. Arguments that use generic parameters on methods use double grave accent characters “``” followed by the zero-based index of the type-parameter instead of the single grave accent used for parameters on types. Arguments that refer to constructed generic types are encoded using the generic type followed by a comma-separated list of type arguments, enclosed by braces “{" and “}”.

E.3.2 ID string examples

The following examples each show a fragment of C# code, along with the ID string produced from each source element capable of having a documentation comment:

- Types are represented using their fully qualified name.

{
    interface IProcess { … }

    class Widget: IProcess
    {
        public class NestedClass { … }
    }
}
public interface IMenuItem { ...
    public delegate void Del(int i);
    public enum Direction { North, South, East, West }
}

Instance variable `<c>y</c>` represents the Point's y-coordinate.

This constructor initializes the new Point to (0,0).

This constructor initializes the new Point to (<paramref name="xor"/>,<paramref name="yor"/>).

The new Point's x-coordinate.

The new Point's y-coordinate.

This method changes the point's location to the given coordinates.

The new x-coordinate.

The new y-coordinate.

The relative x-offset.

The relative y-offset.

This method changes the point's location by the given x- and y-offsets.

This method determines whether two Points have the same location.

The object to be compared to the current object.

True if the Points have the same location; otherwise, false.

Computes the hash code for a Point.

A hash code computed from the x and y coordinates.

The following code:

```csharp
Point p = new Point(3,5);
p.Translate(-1,3);
```

results in `<c>p</c>`'s having the value (2,8).

The relative x-offset.

The relative y-offset.

The new Point's x-coordinate.

The new Point's y-coordinate.

This method changes the point's location to the given coordinates.

This method changes the point's location by the given x- and y-offsets.

This method determines whether two Points have the same location.
Report a point's location as a string.

Of course, I'd be happy to help you understand this page from the C# Language Specification. It seems to be discussing various operators in C#. Here's a breakdown of what you're seeing:

- **Binary Operators**
  - `+` (addition)
  - `-` (subtraction)
  - `*` (multiplication)
  - `/` (division)
  - `%` (modulus)
  - `+=` (increment assignment)
  - `-=` (decrement assignment)
  - `==` (equality)
  - `!=` (inequality)
  - `>` (greater than)
  - `>=` (greater than or equal to)
  - `<` (less than)
  - `<=` (less than or equal to)
  - `^=` (bitwise exclusive OR assignment)

- **Unary Operators**
  - `!` (logical NOT)
  - `~` (bitwise NOT)
  - `&` (address-of)
  - `*` (dereference)
  - `@` (null-coalescing)
  - `??` (null-coalescing assignment)
  - `??` (NULL-coalescing assignment)
  - `=>` (arrow)

- **Postfix Operators**
  - `++` (prefix increment)
  - `--` (prefix decrement)
  - `()` (method call)

- **Prefix Operators**
  - `?` (conditional)
  - `:` (binary conditional)

This page is essentially a reference guide for understanding the syntax and semantics of operators in C#. It's a comprehensive resource for developers who need to understand the language at a deeper level.
